SUPERACID CHEMISTRY
In memory of Katherine Bogdanovich Loker, Benefactor and Friend
CONTENTS

Preface to the Second Edition xvii
Preface to the First Edition xix

1. General Aspects 1

1.1. Defining Acidity 1
   1.1.1. Acids and Bases 1
   1.1.2. The pH Scale 3
   1.1.3. Acidity Functions 4

1.2. Definition of Superacids 6
   1.2.1. Range of Acidities 7

1.3. Types of Superacids 9
   1.3.1. Primary Superacids 10
   1.3.2. Binary Superacids 10
   1.3.3. Ternary Superacids 10
   1.3.4. Solid Superacids 10

1.4. Experimental Techniques for Acidity Measurements (Protic Acids) 11
   1.4.1. Spectrophotometric Method 11
   1.4.2. Nuclear Magnetic Resonance Methods 13
      1.4.2.1. Chemical Shift Measurements 15
      1.4.2.2. Exchange Rate Measurements Based on Line-Shape Analysis (DNMR: Dynamic Nuclear Magnetic Resonance) 18
   1.4.3. Electrochemical Methods 20
   1.4.4. Chemical Kinetics 20
   1.4.5. Heats of Protonation of Weak Bases 22
   1.4.6. Theoretical Calculations and Superacidity in the Gas Phase 22
   1.4.7. Estimating the Strength of Lewis Acids 23
   1.4.8. Experimental Techniques Applied to Solid Acids 27

2. Superacid Systems  

2.1. Primary Superacids  

2.1.1. Brønsted Superacids  

2.1.1.1. Perchloric Acid  

2.1.1.2. Chlorosulfuric Acid  

2.1.1.3. Fluorosulfuric Acid  

2.1.1.4. Perfluoroalkanesulfonic Acids  

2.1.1.5. Hydrogen Fluoride  

2.1.1.6. Carborane Superacids \( H(CB_{11}HR_5X_6) \)  

2.1.2. Lewis Superacids  

2.1.2.1. Antimony Pentafluoride  

2.1.2.2. Arsenic Pentafluoride  

2.1.2.3. Phosphorus Pentafluoride  

2.1.2.4. Tantalum and Niobium Pentafluoride  

2.1.2.5. Boron Trifluoride  

2.1.2.6. Tris(pentafluorophenyl) Borane  

2.1.2.7. Boron Tris(trifluoromethanesulfonate)  

2.1.2.8. Aprotic Organic Superacids  

(\textit{Vol’pin’s Systems})  

2.2. Binary Superacids  

2.2.1. Binary Brønsted Superacids  

2.2.1.1. Hydrogen Fluoride–Fluorosulfuric Acid  

2.2.1.2. Hydrogen Fluoride–Trifluoromethanesulfonic Acid  

2.2.1.3. Tetra(Hydrogen Sulfato)Boric Acid–Sulfuric Acid  

2.2.2. Conjugate Brønsted–Lewis Superacids  

2.2.2.1. Oleums–Polysulfuric Acids  

2.2.2.2. Fluorosulfuric Acid–Antimony Pentafluoride  

(“Magic Acid”)  

2.2.2.3. Fluorosulfuric Acid–Sulfur Trioxide  

2.2.2.4. \( HSO_3F–MF_5(SO_3F)_{5–n} \) \( n = 3, 4, \) \( M = \text{Nb, Ta} \)  

2.2.2.5. Fluorosulfuric Acid–Arsenic Pentafluoride  

2.2.2.6. Perfluoroalkanesulfonic Acid–Based Systems  

2.2.2.7. Hydrogen Fluoride–Antimony Pentafluoride  

(\textit{Fluoroantimonic Acid})  

2.2.2.8. Hydrogen Fluoride–Phosphorus Pentafluoride  

2.2.2.9. Hydrogen Fluoride–Tantalum Pentafluoride
2.2.2.10. Hydrogen Fluoride–Boron Trifluoride
(Tetrafluoroboric Acid) 60

2.2.2.11. Conjugate Friedel-Crafts Acids (HX–AlX₃, etc.) 61

2.3. Ternary Superacids 62

2.3.1. HSO₃F–HF–SbF₅ 62

2.3.2. HSO₃F–HF–CF₃SO₃H 63

2.3.3. CF₃SO₃H–HF–Lewis Acid 63

2.3.4. HSO₃F–SbF₅–SO₃ 63

2.4. Solid Superacids 63

2.4.1. Zeolitic Acids 64

2.4.2. Polymeric Resin Sulfonic Acids 65

2.4.2.1. Lewis Acid-Complexed Sulfonic Acid Resins 65

2.4.2.2. Perfluorinated Polymer Resin Acids 66

2.4.3. Enhanced Acidity Solids 68

2.4.3.1. Bronsted Acid-Modified Metal Oxides:
TiO₂–H₂SO₄, ZrO₂–H₂SO₄ 68

2.4.3.2. Lewis Acid-Modified Metal Oxides
and Mixed Oxides 69

2.4.3.3. Lewis Acid-Complexed Metal Salts 70

2.4.4. Immobilized Superacids (Bound to Inert Supports) 71

2.4.4.1. Superacids Immobilized on Solid Supports 71

2.4.4.2. Graphite-Intercalated Superacids 72

2.4.4.3. SbF₅-Fluorinated Graphite, SbF₅-Fluorinated Al₂O₃ 74

More than 20 years passed since the publication of our book on Superacids. The book became out of print and much progress since was made in the field, which is gaining increasing interest and significance. Hence, it seems warranted to provide the interested reader with a comprehensively updated review and discussion of the field with literature coverage until early 2008. The title has been changed to “Superacid Chemistry” to reflect enormous progress in the field. Some aspects of superelectrophilic activation are also discussed (for more elaborate coverage, readers are referred to G. A. Olah and D. A. Klump, “Superelectrophiles and Their Chemistry” Wiley-Interscience, 2008). Our friend and colleague, Árpád Molnár joined us as a coauthor and made an outstanding contribution to the revised new edition of our book, which we hope will be of interest and use to the chemical community. Our publisher is thanked for arranging the new revised edition.

October 2008
The chemistry of superacids, that is, of acid systems stronger than conventional strong mineral Brønsted acids such as sulfuric acid or Lewis acids like aluminum trichloride, has developed in the last two decades into a field of growing interest and importance. It was J. B. Conant who in 1927 gave the name “superacids” to acids that were capable of protonating certain weak bases such as carbonyl compounds and called attention to acid systems stronger than conventional mineral acids. The realization that Friedel–Crafts reactions are, in general, acid catalyzed with conjugate Lewis–Brønsted acid systems frequently acting as the de facto catalysts extended the scope of acid catalyzed reactions. Friedel–Crafts acid systems, however, are usually only $10^3$ to $10^6$ times stronger than 100% sulfuric acid. The development in the early 1960s of Magic Acid, fluoroantimonic acid, and related conjugate superacids, $10^7$ to $10^{10}$ times stronger than sulfuric acid, added a new dimension to and revival of interest in superacids and their chemistry. The initial impetus was given by the discovery that stable, long-lived, electron-deficient cations, such as carbocations, acidic oxonium ions, halonium ions, and halogen cations, can be obtained in these highly acidic systems. Subsequent work opened up new vistas of chemistry and a fascinating, broad field of chemistry is developing at superacidities. Because acidity is a term related to a reference base, superacidity allows extension of acid-catalyzed reactions to very weak bases and thus extends, for example, hydrocarbon chemistry to saturated systems including methane.

Some years ago in two review articles (Science 206, 13, 1979; La Recherche 10, 624, 1979), we briefly reviewed some of the emerging novel aspects of superacids. However, we soon realized that the field was growing so fast that to be able to provide a more detailed survey for the interested chemist a more comprehensive review was required. Hence, we welcomed the suggestion of our publisher and Dr. Theodore P. Hoffman, chemistry editor of Wiley-Interscience, that we write a monograph on superacids.

We are unable to thank all of our friends and colleagues who directly or indirectly contributed to the development of the chemistry of superacids. The main credit goes to all researchers in the field whose work created and continues to enrich this fascinating area of chemistry. Professor R. J. Gillespie’s pioneering work on the inorganic chemistry of superacids was of immense value and inspiration to the development of the whole field. Our specific thanks are due to Drs. David Meidar and Khosrow Laali, who helped with the review of solid superacid systems and their reactions. Professor E. M. Arnett is thanked for reading part of our manuscript and for his thoughtful comments.
Finally we would like to thank Mrs. R. Choy, who tirelessly and always cheerfully typed the manuscript.

CHAPTER 1

General Aspects

1.1. DEFINING ACIDITY

1.1.1. Acids and Bases

The concept of acidity was born in ancient times to describe the physiological property such as taste of food or beverage (in Latin: \textit{acidus}, sour; \textit{acetum}, vinegar). Later during the development of experimental chemistry, it was soon realized that mineral acids such as sulfuric, nitric, and hydrochloric acids played a key role in chemical transformations. Our present understanding of acid-induced or -catalyzed reactions covers an extremely broad field ranging from large-scale industrial processes in hydrocarbon chemistry to enzyme-controlled reactions in the living cell.

The chemical species that plays a unique and privileged role in acidity is the hydrogen nucleus, that is, the proton: \( \text{H}^+ \). Since its 1s orbital is empty, the proton is not prone to electronic repulsion and by itself has a powerful polarizing effect. Due to its very strong electron affinity, it cannot be found as a free “naked” species in the condensed state but is always associated with one or more molecules of the acid itself or of the solvent. Free protons exist only in the gas phase (such as in mass spectrometric studies). Regardless, as a shorthand notation, one generally depicts the proton in solution chemistry as “\( \text{H}^+ \).” Due to its very small size (10^5 times smaller than any other cation) and the fact that only the 1s orbital is used in bonding by hydrogen, proton transfer is a very facile chemical reaction and does not necessitate important reorganization of the electronic valence shells. Understanding the nature of the proton is important while generalizing quantitative relationships in acidity measurements.\(^1\)\(^2\)

The first clear definition of acidity can be attributed to Arrhenius, who between 1880 and 1890 elaborated the theory of ionic dissociation in water to explain the variation in strength of different acids.\(^3\) Based on electrolytic experiments such as conductance measurements, he defined acids as substances that dissociate in water and yield the hydrogen ion whereas bases dissociate to yield hydroxide ions. In 1923, J. N. Brønsted generalized this concept to other solvents.\(^4\) He defined an acid as a species that can donate a proton and defined a base as a species that can accept it. This
The definition is generally known as the Brønsted–Lowry concept. The dissociation of an acid HA in a solvent S can be written as an acid–base equilibrium [Eq. (1.1)].

\[
HA + S \rightleftharpoons A^- + SH^+ \tag{1.1}
\]

The ionization of the acid HA in solvent S leads to a new acid HS\(^+\) and a base A\(^-\). Equation (1.1) has a very wide scope and can be very well applied to neutral and positively and negatively charged acid systems. The acid–base pair that differs only by a proton is referred to as the conjugate acid–base pair. Thus, H\(_2\)O is the conjugate base of the acid H\(_3\)O\(^+\). An obvious consequence of the concept is that the extent to which an acid ionizes depends on the basicity of the solvent in which the ionization takes place. This shows the difficulty in establishing an absolute acidity scale. Acidity scales are energy scales, and thus they are arbitrary with respect to both the reference point and the magnitude of units chosen.

Fortunately, many of the common solvents by themselves are capable of acting as acids and bases. These amphoteric or amphiprotic solvents undergo self-ionization [e.g., Eqs. (1.2) and (1.3)], which can be formulated in a general way as in Eq. (1.4).

\[
\begin{align*}
2 \text{H}_2\text{O} & \rightleftharpoons \text{H}_3\text{O}^+ + \text{OH}^- \tag{1.2} \\
2 \text{HF} & \rightleftharpoons \text{H}_2\text{F}^+ + \text{F}^- \tag{1.3} \\
2 \text{HA} & \rightleftharpoons \text{H}_2\text{A}^+ + \text{A}^- \tag{1.4}
\end{align*}
\]

This equilibrium is characterized by the autoprotolysis constant \(K_{ap}\), which under the usual high dilution conditions can be written as in Eq. (1.5).

\[
K_{ap} = \left[\text{H}_2\text{A}^+\right]\left[\text{A}^-\right] \tag{1.5}
\]

Indeed the extent of dissociation of the solvent is very small (in HF, \(K_{ap} \approx 10^{-11}\); in H\(_2\)O, \(K_{ap} = 10^{-14}\)). The p\(K_{ap}\) value that gives the acidity range will be discussed later.

G.N. Lewis extended and generalized the acid–base concept to nonprotonic systems.\(^{5,6}\) He defined an acid as a substance that can accept electrons and defined a base as a substance that can donate electrons. Lewis acids are electron-deficient molecules or ions such as BF\(_3\) or carbocations, whereas Lewis bases are molecules that contain readily available nonbonded electron pairs (as in ethers, amines, etc.) [Eq. (1.6)].

\[
\text{BF}_3 + :\text{O(CH}_3\text{)}_2 \rightleftharpoons \text{BF}_3:\text{O(CH}_3\text{)}_2 \tag{1.6}
\]

Of course, in a generalized way, the proton H\(^+\) is also a Lewis acid and the Brønsted acids and bases also fall into the Lewis categories.

Considering the general equation (1.4) for the auto-ionization of solvent HA, one can define an acid as any substance that will increase \([\text{H}_2\text{A}^+]\) and define a base as any substance that will increase \([\text{A}^-]\) and thus decrease \([\text{H}_2\text{A}^+]\). This definition, which includes both Lewis’ and Brønsted’s concepts, is used in practice while measuring the acidity of a solution by pH.
A number of strategies have been developed for acidity measurements of both aqueous and nonaqueous solutions. We will briefly review the most important ones and discuss their use in establishing acidity scales.

1.1.2. The pH Scale

The concentration of the acid itself is of little significance other than analytical, with the exception of strong acids in dilute aqueous solutions. The concentration of $H^+$ itself is not satisfactory either, because it is solvated diversely and the ability of transferring a proton to another base depends on the nature of the medium. The real physical quantity describing the acidity of a medium is the activity of the proton $a_{H^+}$. The experimental determination of the activity of the proton requires the measurement of the potential of a hydrogen electrode or a glass electrode in equilibrium with the solution to be tested. The equation is of the following type [Eq. (1.7)], wherein $C$ is a constant.

$$E = C - \frac{RT}{F} \log_{10}(a_{H^+}) \quad (1.7)$$

It was Sørensen’s idea to use this relationship, which can be considered as a basis to the modern definition of the pH scale of acidity for aqueous solutions. The pH of a dilute solution of acid is related to the concentration of the solvated proton from Eq. (1.8). Depending on the dilution, the proton can be further solvated by two or more solvent molecules.

$$pH = -\log[HS^+] \quad (1.8)$$

When the acid solution is highly diluted in water, the pH measurement is convenient, but it becomes critical when the acid concentration increases and, even more so, if nonaqueous media are employed. Since a reference cell is used with a liquid junction, the potential at the liquid junction also has to be known. The hydrogen ion activity cannot be measured independently, and for this reason the equality of Eq. (1.9) cannot be definitely established for any solution.

$$pH = -\log_{10}(a_{H^+}) \quad (1.9)$$

Under the best experimental conditions, the National Bureau of Standard has set up a series of standard solutions of pH from which the pH of any other aqueous solution can be extrapolated as long as the ionic strength of the solution is not higher than 0.1 $M$. For more concentrated solutions, the pH scale will no longer have any real significance. In extending the limit to 1 $M$ solutions, it is apparent that the available range of acidity is directly related to the autoprotolysis constant [Eq. (1.5)], because the minimum value of pH in a solution is zero and the maximum value is $pK_{ap} = p(H_2A^+) + p(A^-)$. Thus, the range of pH ($\Delta pH$) is $pK_{ap}$ (for water, 14 pH units). These limiting conditions are rather unfortunate because many chemical transformations are achieved beyond this range and under much less ideal conditions.
1.1.3. Acidity Functions

Considering the limited applicability of the pH scale, a quantitative scale is needed to express the acidity of more concentrated or nonaqueous solutions.

A knowledge of the acidity parameter should permit one to estimate the degree of transformation of a given base (to its protonated form) in its conjugate acid. This should allow one to relate these data to the rate of acid-catalyzed reactions. Hammett and Deyrup in 1932 were the first to suggest a method for measuring the degree of protonation of weakly basic indicators in acid solution. The proton transfer equilibrium in the acid solution between an electro-neutral weak base B and the solvated proton can be written as in Eq. (1.10).

\[
B + H_2A^+ \rightleftharpoons BH^+ + AH
\] (1.10)

Bearing in mind that the proton is solvated (\(AH_2^+\)) and that AH is the solvent, the equilibrium can be written as in Eq. (1.11).

\[
B + H^+ \rightleftharpoons BH^+
\] (1.11)

The corresponding thermodynamic equilibrium constant is \(K_{BH^+}\), which is expressed as in Eq. (1.12), in which \(a\) is the activity, \(C\) the concentration, and \(f\) the activity coefficient.

\[
K_{BH^+} = \frac{a_{H^+} \cdot a_B}{a_{BH^+}} = \frac{a_{H^+} \cdot C_B}{C_{BH^+} \cdot f_{BH^+}}
\] (1.12)

From this equation, Eq. (1.13) follows.

\[
\frac{C_{BH^+}}{C_B} = \frac{1}{K_{BH^+}} \cdot \frac{a_{H^+} \cdot f_B}{f_{BH^+}}
\] (1.13)

Because the first ratio represents the degree of protonation, Hammett and Deyrup defined the acidity function \(H_0\) by Eq. (1.14).

\[
H_0 = -\log a_{H^+} \cdot \frac{f_B}{f_{BH^+}} = -\log K_{BH^+} + \log \frac{C_B}{C_{BH^+}}
\] (1.14)

Equation (1.14) can be written for further discussion in the more usual form of Eq. (1.15).

\[
H_0 = pK_{BH^+} - \log \frac{[BH^+]}{[B]}
\] (1.15)

From Eq. (1.14) it is clear that in dilute aqueous solution, as the activity coefficients tend to unity, the Hammett acidity function becomes identical with pH. On the other hand, by making the fundamental assumption that the ratio \(f_B/f_{BH^+}\) is the same for different bases in a given solution, Hammett postulated that the \(H_0\) function was unique.
for a particular series of solutions of changing acidity. The first application was made for the H$_2$SO$_4$–H$_2$O system using a series of primary anilines as indicators. By starting with the strongest base B$_1$, the p$K_{B_1H^+}$ was measured in dilute aqueous solution. The p$K$ of the next weaker base B$_2$ was then determined by measuring the ionization ratio of the two indicators in the same acid solution using the relation of Eq. (1.16).

$$pK_{B_1H^+} - pK_{B_2H^+} = \log \frac{[B_1H^+]}{[B_1]} - \log \frac{[B_2H^+]}{[B_2]}$$  (1.16)

The ionization ratio was measured by UV–visible spectroscopy. With the help of successively weaker primary aromatic amine indicators, the strongest base being para-nitroaniline (p$K = 1.40$) and the weakest trinitroaniline (p$K = -9$), Hammett explored the whole H$_2$O–H$_2$SO$_4$ range up to 100% sulfuric acid and the perchloric acid–water solution up to 60% of acid. Similar acidity functions such as H$_-$, H$_+$, H$_2+$ were proposed related to acid–base equilibria in which the indicator is negatively, positively, or even dipositively charged. The validity of all of these functions is based on the simple assumption that the activity coefficient ratio is independent of the nature of the indicator at any given solvent composition. In this case the log $[BH^+]/[B]$ plots against $H_0$ should be linear with a slope of $-1.00$ for all neutral bases. This is not the case for groups of indicators with different structures, and especially for different basic sites, which often show significant deviations. For this reason, it is well recognized now that the above assumption does not have a general validity. The measurement of a Hammett acidity function should be limited to those indicators for which log $[BH^+]/[B]$ plotted against $H_0$ gives a straight line with a negative unit slope. These indicators are called Hammett bases.

Equilibria other than proton transfer have also been used to determine acidity functions. One of these is based on the ionization of alcohols (mainly arylmethyl alcohols) in acid solution following the equilibrium in Eq. (1.17).

$$\text{ROH} + H^+ \rightleftharpoons R^+ + H_2O$$  (1.17)

The corresponding acidity function described as $H_R$ is then written in Eq. (1.18).

$$H_R = pK_{R^+} - \log \frac{[R^+]}{[\text{ROH}]}$$  (1.18)

This $H_R$ function, also called $J_0$ function, has also been used to measure the acidity of the sulfuric acid–water and perchloric acid–water systems. It shows a large deviation from the $H_0$ scale in the highly concentrated solutions as shown in Figure 1.1.

However, all these and other acidity functions are based on Hammett’s principle and can be expressed by Eq. (1.19), in which B and A are the basic and the conjugate acidic form of the indicator, respectively. They become identical with the pH scale in highly dilute acid solutions. The relative and absolute validity of the different acidity functions have been the subject of much controversy and the subject has been extensively reviewed.  

1.10–14
Whatever may be the limitations of the concept first proposed by Hammett and Deyrup in 1932 until now, no other widely used alternative has appeared to better assess quantitatively the acidity of concentrated and nonaqueous strongly acidic solutions. The experimental methods that have been used to determine acidity functions are discussed in Section 1.4.

1.2. DEFINITION OF SUPERACIDS

It was in a paper (including its title) published in 1927 by Hall and Conant in the *Journal of the American Chemical Society* that the name “supercid” appeared for the first time in the chemical literature. In a study of the hydrogen ion activity in a nonaqueous acid solution, these authors noticed that sulfuric acid and perchloric acid in glacial acetic acid were able to form salts with a variety of weak bases such as ketones and other carbonyl compounds. These weak bases did not form salts with the aqueous solutions of the same acids. The authors ascribed this high acidity to the ionization of these acids in glacial acetic acid, increasing the concentration of \( \text{CH}_3\text{COOH}_2^+ \), a species less solvated than \( \text{H}_3\text{O}^+ \) in the aqueous acids. They proposed

\[
H_A = pK_A - \log \frac{A}{B} \tag{1.19}
\]
to call these solutions “superacid solutions.” Their proposal was, however, not further followed up or used until the 1960s, when Olah’s studies of obtaining stable solutions of highly electron-deficient ions, particularly carbocations, focused interest on very high-acidity nonaqueous systems.\textsuperscript{16,17} Subsequently, Gillespie proposed an arbitrary but since widely accepted definition of superacids,\textsuperscript{18,19} defining them as any acid system that is stronger than 100\% sulfuric acid, that is, $H_0 \leq -12$. Fluorosulfuric acid and trifluoromethanesulfonic acid are examples of Brönsted acids that exceed the acidity of sulfuric acid with $H_0$ values of about $-15.1$ and $-14.1$, respectively.

To reach acidities beyond this limit, one has to start with an already strong acid ($H_0 \approx -10$) and add to it a stronger acid that increases the ionization. This can be achieved either by adding a strong Brönsted acid (HB) capable of ionizing in the medium [Eq. (1.20)] or by adding a strong Lewis acid (L) that, by forming a conjugate acid, will shift the autoprotonation equilibrium by forming a more delocalized counterion of the strong acid [Eq. (1.21)].

$$
\text{HA} + \text{HB} \quad \leftrightarrow \quad \text{H}_2\text{A}^+ + \text{B}^- \quad (1.20)
$$

$$
2\text{HA} + \text{L} \quad \leftrightarrow \quad \text{H}_2\text{A}^+ + \text{LA}^- \quad (1.21)
$$

In both cases, a remarkable acidity increase is observed from the $H_0$ value of the neat HA as shown in Figure 1.2 for HSO$_3$F.

It is this large acidity jump, generally more than 5 $H_0$ units, that raises a strong acid solution into the superacid region. Therefore, it is clear that the proposed reference of $H_0 = -12$ for the lower limit of superacidity is only arbitrary. It could as well be $H_0 = -15.1$ with HF or HSO$_3$F as solvent.

Gillespie’s definition of superacids relates to Brönsted acid systems. Because Lewis acids also cover a wide range of acidities extending beyond the strength of conventionally used systems, Olah suggested the use of anhydrous aluminum chloride as the arbitrary reference and we categorize Lewis superacids as those stronger than aluminum chloride\textsuperscript{17} (see, however, subsequent discussion on the difficulties of measuring the strength of a Lewis acid).

It should be also noted that in biological chemistry, following a suggestion by Westheimer,\textsuperscript{20} it is customary to call catalysis by metal ions bound to enzyme systems as “superacid catalysis.” Because the role of a metal ion is analogous to a proton, this arbitrary suggestion reflects enhanced activity and is in line with previously discussed Brönsted and Lewis superacids.

### 1.2.1. Range of Acidities

Despite the fact that superacids are stronger than 100\% sulfuric acid, there may be as much or more difference in acidity between various superacid systems than between neat sulfuric acid and its 0.1 $M$ solution in water.

Acidity levels as high as $H_0 = -27$ have been estimated on the basis of exchange rate measurements by NMR for an HSO$_3$F–SbF$_5$ mixture containing 90 mol\% SbF$_5$.\textsuperscript{21} In fact, the HF–SbF$_5$ is considered one of the strongest superacid system based on
various measurements. Meanwhile, however, Sommer and coworkers found that the weakest basic indicator of the para-methoxybenzhydryl cation family (4,4'-dimethoxy; $pK_{BH^+} \approx -23$) could not be diprotonated even in the strongest HF–SbF$_5$ acid.\textsuperscript{22} For this reason it appears that one should not expect acidity levels higher than approximately $H_0 = -24$ in the usual superacid systems (Figure 1.3). Predictions of stronger acidities are all based on indirect estimations rather than direct acid–base equilibria measurements. It is important to recognize that the naked proton “$H^+$” is not present in the condensed phase because even compounds as weakly basic as methane or even rare gases bind the proton.\textsuperscript{23,24}

A quantitative determination of the strength of Lewis acids to establish similar scales ($H_0$) as discussed in the case of protic (Brønsted-type) superacids would be most useful. However, to establish such a scale is extremely difficult. Whereas the Brønsted acid–base interaction invariably involves a proton transfer reaction that allows meaningful comparison, in the Lewis acid–base interaction, involving for example Lewis acids with widely different electronic and steric donating substituents, there is no such common denominator.\textsuperscript{25,26} Hence despite various attempts, the term “strength of Lewis acid” has no well-defined meaning.
Regardless, it is important to keep in mind that superacidity encompasses both Brønsted and Lewis acid systems and their conjugate acids. The qualitative picture of Lewis acid strengths will be discussed in Section 1.4.7.

The acidity strength of solid acids is still not well known and is difficult to measure. Claims of superacidity in solids are numerous and will be discussed later in Chapter 2. Among the reviews related to acidity characterization of solids, those of Corma, Farneth and Gorte, and Fripiat and Dumesic are quite significantly representative.

1.3. TYPES OF SUPERACIDS

As discussed, superacids, similar to conventional acid systems, include both Brønsted and Lewis acids and their conjugate systems. Protic (Brønsted-type) superacids include strong parent acids and the mixtures thereof, whose acidity can be further enhanced by various combinations with Lewis acids (conjugate acids). The following are the most frequently used superacids.

![Figure 1.3. Acidity ranges for the most common superacids. The solid and open bars are measured using indicators; the broken bar is estimated by kinetic measurements; numbers in parentheses indicate mol% Lewis acid.](image)
1.3.1. Primary Superacids

1. Brønsted superacids such as perchloric acid (HClO₄), halosulfuric acids (HSO₃Cl, HSO₃F), perfluoroalkanesulfonic acids (CF₃SO₃H, R₅SO₃H), hydrogen fluoride, and carborane superacids [H(CB₁₁HR₅X₆)].

2. Lewis superacids, such as SbF₅, AsF₅, PF₅, TaF₅, NbF₅, BF₃, tris(pentafluorophenyl) borane, boron tris(trifluoromethanesulfonate), and aprotic organic superacids developed by Vol’pin and co-workers.

1.3.2. Binary Superacids

1. Binary Brønsted superacids such as HF–HSO₃F, HF–CF₃SO₃F, and HB(HSO₄)₄.

2. Conjugate Brønsted–Lewis superacids:
   a. Combination of oxygenated Brønsted acids (H₂SO₄, HSO₃F, CF₃SO₃H, R₅SO₃H) with Lewis acids (SO₃, SbF₅, AsF₅, TaF₅, and NbF₅);
   b. Hydrogen fluoride in combination with fluorinated Lewis acids such as SbF₅, PF₅, TaF₅, NbF₅, and BF₃;
   c. Conjugate Friedel–Crafts acids such as HBr–AlBr₃ and HCl–AlCl₃.

1.3.3. Ternary Superacids

Examples are HSO₃F–HF–SbF₅, HSO₃F–HF–CF₃SO₃H, and HSO₃F–SbF₅–SO₃.

1.3.4. Solid Superacids

The acid–base character of solids was studied very early by Tanabe’s group³¹,³² and was first described in a landmark volume.³³

Solid superacids can be further divided into various groups depending on the nature of the acid sites. The acidity may be a property of the solid as part of its chemical structure (possessing Lewis or Brønsted sites; the acidity of the latter can be further enhanced by complexing with Lewis acids). Solid superacids can also be obtained by deposition on or intercalation of strong acids into an otherwise inert or low-acidity support.

1. Zeolitic acids.

2. Polymeric resin sulfonic acids including sulfonic acid resins complexed with Lewis acids and perfluorinated polymer resin acids (Nafion–H and Nafion–silica nanocomposites).

3. Enhanced acidity solids including Brønsted and Lewis acid-modified metal oxides and mixed oxides, as well as metal salts complexed with Lewis acids.

4. Immobilized superacids and graphite-intercalated superacids.

As with previous classifications, these are also arbitrary and are suggested for practical discussion of an otherwise rather complex field. The superacid character of
solids is discussed later in subsequent subchapters, and individual superacid systems are discussed in Chapter 2.

1.4. EXPERIMENTAL TECHNIQUES FOR ACIDITY MEASUREMENTS (PROTIC ACIDS)

From Eq. (1.14) it is apparent that the main experimental difficulty in determining acidities is the estimation of the ratio between the free base and its protonated ionic form of a series of indicators, their so-called ionization ratios.

1.4.1. Spectrophotometric Method

In the early work of Hammett and Deyrup the measurement of the ionization ratio was based on the color change of the indicator. The solutions containing the indicator were compared at 25°C in a colorimeter with a standard reference. This reference was water, when the indicator was colorless in its acid form, and 96% sulfuric acid (or 70% perchloric acid), when the indicator was colorless in the basic form.

For example, when the indicator was colored in water the authors define a stoichiometric color intensity relative to water \( I_w = \frac{C_w}{C_a} \), where \( C_a \) and \( C_w \) are the stoichiometric concentrations of indicator in solution A and in water. On the other hand, the specific color intensity of the colored form relative to water is defined as \( S_w = \frac{[B]_w}{[B]_a} \), where \([B]_w\) is the concentration of the colored base in water and \([B]_a\) is concentration in solution A. Because the indicator exists only in its basic form in water, \([B]_w = C_w\); and in solution A, \( C_a = [B]_a + [BH^+]_a \). The ionization ratio is given by Eq. (1.22).

\[
\frac{[BH^+]}{[B]} = \frac{S_w - I_w}{I_w} \quad (1.22)
\]

Despite seven decades of technical and scientific progress, the original Hammett method has not become obsolete. The colorimeter has been replaced by modern spectrophotometers that can be operated at selected wavelengths extending the spectra beyond visible into the ultraviolet region of the electromagnetic spectrum. The experimental variable, which is wavelength-dependent, is the optical density \( D \). \( D \) is related to the concentration by the Beer–Lambert law [Eq. (1.23)].

\[
D_{i,\lambda} = \varepsilon_{i,\lambda} C_i l \quad (1.23)
\]

\( C_i \) is the concentration of the absorbing species, \( l \) is the length of the cell, and \( \varepsilon_i \) is the molar absorptivity (or extinction coefficient). If at a given wavelength \( \lambda \), \( \varepsilon_{BH^+} \), \( \varepsilon_B \), and \( \varepsilon_\lambda \) are the extinction coefficients, respectively, of acid form of the indicator, its basic form, and of the unknown solution, the ionization ratio is given by Eq. (1.24).

\[
\frac{[BH^+]}{[B]} = \frac{\varepsilon_B - \varepsilon_\lambda}{\varepsilon_\lambda - \varepsilon_{BH^+}} \quad (1.24)
\]
For a greater precision in this determination, \( \lambda \) should be chosen so as to have the maximum difference between \( \varepsilon_{B^+} \) and \( \varepsilon_B \). For this reason, the areas between the absorption line and the baseline of both acidic and basic forms of the indicator should be measured and compared.

Whereas the precision of the method is generally excellent, a number of drawbacks may appear with some indicators. First, Eq. (1.24) is true only with the assumption that \( \varepsilon_{B^+} \) is solvent-independent (it is clear that \( \varepsilon_B \) and \( \varepsilon_{B^+} \) cannot be measured separately in the same solution). The medium effect on the absorption spectrum (mainly the wavelength shift of \( \lambda_{\text{max}} \)) can be easily taken into account in the measurements. However, large changes in the absorption spectrum during the increase in ionization are difficult to correct. Another difficulty that might appear is the structural change of the indicator, during or after protonation. The change in temperature, however, has been shown in the H\(_2\)SO\(_4\)–H\(_2\)O system to have little effect on the \( H_0 \) value\(^{34} \) but the \( pK_{B^+} \) and the ionization ratios are more sensitive.

The \( pK_{B^+} \) value is easy to determine, when the ionization ratio can be measured in dilute aqueous solution [Eq. (1.25)].

\[
pK_{B^+} = \lim_{(HA \to 0)} \log \left( \frac{[BH^+]}{[B]} \right) - \log[H_3O^+] \tag{1.25}
\]

It is to be noted that when the acid solution is very dilute, the presence of the indicator modifies the acidity: \( [H_3O^+] = [HA] - [B] \), and thus the concentration of the indicator has to be taken into account.

As is apparent from Eq. (1.14), an indicator is only useful over an acidity range where its ionization ratio can be measured experimentally with sufficient precision. For spectrophotometric method, this means approximately 2 log units per indicator. Accordingly, the direct determination of the \( pK_{B^+} \) value of an indicator in concentrated solution is not possible. It is actually achieved by the method developed by Hammett in his early work using a series of indicators of overlapping range.\(^8 \) Taking into account the overlapping of each indicator with the preceding and the following one, each of which is useful for 2 log units, it appears that several indicators are necessary (approximately as many indicators as the number of desired log units). This is illustrated in Figure 1.4.

Paul and Long\(^{35} \) have tabulated \( pK_{B^+} \) values for indicators, which were used to establish Hammett acidity functions for aqueous acids between the years 1932 and 1957. The data were summarized as a set of “best values” of \( pK_{B^+} \) for the bases. Since then, subsequent work seems to suggest that some of these values are incorrect. This is particularly the case for some of the weaker bases whose quoted \( pK_{B^+} \) were based on a stepwise extrapolation of results of some indicators that have since been proven to be unsatisfactory based on the strict definition of \( H_0 \). These data, as well as those for weaker bases that have been studied since, covering the whole acidity range from dilute acid to the superacid media are collected in Table 1.1.
Figure 1.4. The ionization ratio as measured for a series of indicators in the 0–100% H$_2$SO$_4$–H$_2$O system.$^8$

Up to a $H_0$ value of $-10$, all indicators are primary amines and are therefore suitable for the measurement of the Hammett $H_0$ function. For stronger acids, new indicators such as nitro compounds have to be used. Although the acidity function scale based upon nitro compounds as indicators may not be a satisfactory extension of the aniline indicator scale, Gillespie and Peel$^{18}$ have shown that the most basic nitro compound indicator, para-nitrotoluene overlaps in a satisfactory manner with the weakest indicator in the aniline series, 2,4,6-trinitroaniline. Thus, the acidity measurements using the nitro compounds may be considered to give the best semiquantitative picture of the acidity of the various superacid systems.

UV spectroscopy of adsorbed Hammett bases has also been used to estimate the acidity of solids such as zeolites.$^{38}$

### 1.4.2. Nuclear Magnetic Resonance Methods

NMR spectroscopy, which was developed in the late 1950s as a most powerful tool for structural analysis of organic compounds, has also proven to be useful for acidity determinations. The measurement of the ionization ratio has been achieved by a variety of methods demonstrating the versatility of this technique. If we consider the general acid–base equilibrium Eq. (1.26) obtained when the indicator B is dissolved in the strong acid HA, then $k_p$, and $k_d$, respectively, are the rates of protonation and deprotonation.

$$\text{HA} + B \overset{k_p}{\underset{k_d}{\rightleftharpoons}} \text{BH}^+ + A^- \quad (1.26)$$

The thermodynamic equilibrium constant $K$ is related to these rates according to Eq. (1.27).

$$K = \frac{[\text{BH}^+][A^-]}{[\text{HA}][B]} = \frac{k_p}{k_d} \quad (1.27)$$
In NMR spectroscopy, when a species (for example, here $[BH^+]$) is participating in an equilibrium, its spectrum is very dependent on its mean lifetime ($t$).\textsuperscript{39,40} The inverse of the mean lifetime is a first-order rate constant, called the rate of exchange ($k = 1/t$), which can be obtained from the line-shape analysis of the NMR bands if $1 \text{s}^{-1} \leq k \leq 10^3 \text{s}^{-1}$. Three cases can thus be envisaged:

1. “Slow Exchange” Conditions: $k \leq 10^{-2} \text{s}^{-1}$. The species can be observed as if no exchange were taking place.
2. Measurable Exchange Conditions: $1 \text{s}^{-1} < k < 10^3 \text{s}^{-1}$. The rate of exchange can be calculated from the line-shape analysis of the NMR bands of the exchanging species.

3. “Fast Exchange” Conditions: \( k > 10^4 \text{s}^{-1} \). The observed NMR bands appear as the weighted average of the species participating in the equilibrium. Depending on these conditions, various NMR methods have been proposed and used to calculate the ionization ratio of weak bases in a superacid medium.

### 1.4.2.1. Chemical Shift Measurements.

Under “slow-exchange” conditions, the ionization ratio cannot be measured. In fact, one of the major advantages of the superacidic media is the ease with which weak bases can be fully protonated and directly observed by NMR. Because it is known that the protonation rates are practically diffusion-controlled \((\sim 10^9 \text{liter mol}^{-1} \text{s}^{-1})\), under these conditions \((\leq 10^{-2} \text{s}^{-1})\) the indicator is “totally” in the acidic form described by the NMR spectrum and no variable is available to measure the ionization ratio.

Under “fast-exchange” conditions, however, the NMR spectrum presents a weighed average of the bands of the exchanging species, and with the sensitivity limits \((\sim 5\text{–}95\%\)) the ionization ratio can be measured taking the chemical shift as a variable. The calculation is simply based on the observed chemical shift of the average line \((\delta_{\text{obs}})\), provided that the chemical shift of the base indicator \((\delta_B)\) and of its acid form \((\delta_{B\text{H}^+})\) are known \([\text{Eq. (1.28)}]\). This is generally obtained by increasing or decreasing the acidity of the medium.

\[
\delta_{\text{obs}} = \frac{\delta_{B\text{H}^+} [\text{BH}^+] + \delta_B [\text{B}]}{[\text{BH}^+] + [\text{B}]} \quad (1.28)
\]

By plotting the chemical shift variation against the acidity, one observes a typical acid–base titration curve (Figure 1.5) and the \(pK_{B\text{H}^+}\) of the indicator can be determined this way. This NMR method, which was first proposed by Grunwald et al.,\(^4\) has been applied by Levy et al.\(^4\) using various ketones and \(\alpha\)-haloketones for the determination of ketone basicity and evaluation of medium acidity.

Compared with spectrophotometry, the NMR method has a number of advantages: (i) The procedure is very rapid, and it can be used by observing the variation of chemical shifts of diverse nuclei such as \(^1\text{H}, ^{13}\text{C}, ^{19}\text{F}, \text{and} ^{17}\text{O}\). (ii) It is insensitive to colored impurities and slight decomposition of the indicator. (iii) In principle, it can be used over the whole range of known acidity. The medium effect, which may be important in \(^1\text{H}\) NMR, becomes negligible in the case of \(^{13}\text{C}\) NMR spectroscopy. The method can be used with a wide variety of weak bases having a lone-pair containing heteroatoms as well as simple aromatic hydrocarbons.

However, because the measurement of the ionization ratio requires the presence of a minimum of 5% of one of the forms of the indicator, it necessitates the availability of a family of structurally similar compounds of varying basicity to cover a large domain of acidity. This condition has been met by Sommer and co-workers\(^2\) using the para-methoxybenzhydryl cations as useful indicators for the strongest superacids.
Figure 1.5. Acidity-dependent $^1$H NMR chemical shift variations: protonation curve for acetaldehyde.$^{42}$ ● CF$_3$COOH–H$_2$SO$_4$, ▲ CF$_3$COOH–CF$_3$SO$_3$H.

The basicity of these indicators can be controlled by suitable substitution of the phenyl rings effecting ionization of the corresponding benzydrols [Eq. (1.29)]. The protonation equilibria [Eq. (1.30)] is measurable by $^1$H or $^{13}$C NMR spectroscopy.

$$
\begin{align*}
\text{CH}_3 & \quad \text{pK} = -10.2(\pm 0.2) \\
7 & \quad 8 \quad 9 \quad 10 \quad 11 \quad 12 \quad 13 \quad 14
\end{align*}
$$

The basicity of these indicators can be controlled by suitable substitution of the phenyl rings effecting ionization of the corresponding benzydrols [Eq. (1.29)]. The protonation equilibria [Eq. (1.30)] is measurable by $^1$H or $^{13}$C NMR spectroscopy.

$$
\begin{align*}
\text{R} & = 1: 4'-\text{MeO}, 2: 4'-\text{Me}, 3: 4'-\text{H}, 4: 4'-\text{Br}, \\
& 5: 4'-\text{CF}_3, 6: 4'-\text{MeOH}^+
\end{align*}
$$
The protonation curves of indicators 1–4 in the HSO$_3$F–SbF$_5$ system (Figure 1.6) show how the decreasing basicity of the indicator necessitates an increasing amount of SbF$_5$ for half-protonation. The decreasing slope of the inflection point shows also that the increase in acidity by SbF$_5$ addition becomes smaller as more SbF$_5$ is added to the Brønsted acid (as a consequence of oligomeric anion formation).

The same indicators have been used to compare the relative acidity of the three most used superacids. As shown on Figure 1.7, the half-protonation of indicator 3 necessitates 40, 25, and 8 mol% SbF$_5$, respectively, in triflic acid, fluorosulfuric acid, and hydrogen fluoride systems. These results show the supremacy of the HF–SbF$_5$ system in which small concentrations of SbF$_5$ induce a dramatic increase in acidity (see also Section 2.2.2.7).

1.4.2.2. Exchange Rate Measurements Based on Line-Shape Analysis (DNMR: Dynamic Nuclear Magnetic Resonance). Under the measurable exchange rate conditions, two possibilities have been considered:

1. The change in line shape can be directly related to the proton exchange.
2. The change in line shape is due to a separate exchange process related to the proton exchange.

Both methods have been exploited to determine ionization ratios.

**Direct Exchange Rates.** With the assumption that $k_p$ is a constant over the range of measured acidity and $k_{BH^+}$ of a series of overlapping bases remains measurable [Eq. (1.31)] (each base covering approximately 3 log units for a given concentration), Gold et al.21 explored the acidity of the HSO$_3$F–SbF$_5$ system containing up to 90 mol% SbF$_5$. The highest acidity was estimated at $H_0 = -23$ approximately.43

$$H_0 = p_{BH^+} - \log \frac{k_p[HA]}{k_{BH^+}}$$  (1.31)

**Indirect Exchange Rates.** In this case, the line shape is indirectly related to the acid-base equilibrium. Besides measuring intermolecular processes like the proton exchange rates, DNMR often has been used to measure intramolecular processes like conformational changes that occur on the same time scale. When the activation energy of such a process is very different in the acidic and basic forms for an indicator, DNMR can be used to measure the ionization ratio.

Due to a partial $\pi$-character, aromatic carbonyl compounds have an activation energy barrier for rotation around the phenyl–carbonyl bond, the value of which is substantially increased upon protonation.44 In para-anisaldehyde a second protonation of the methoxy group will drastically decrease their barrier. The temperature-dependent NMR spectrum will reflect both exchange processes, intra- and intermolecular, as shown in Scheme 1.1.

A careful analysis of the NMR line shape provides the $BH_2^+/BH^+$ ratio. Because of a large difference in activation energies between the rotation barriers in the mono- and diprotonated aldehyde, the observed rates are very sensitive to the concentration of BH$^+$. Thus ionization ratios of the order of $10^{-4}$ could be measured and approximately 4 log units of $H_0$ could be covered with the same indicator.45

By combining this method with the previously discussed chemical shift method, which is sensitive in the 0.05–20 range for the ionization ratio, the acidity could be measured over more than 5 $H_0$ units with the same indicator. Figure 1.8 shows the complementarity of both methods.

These are only approximate estimations, but are in reasonable agreement with more recent $H_0$ determination by other methods.43

Despite the evident advantages of the NMR methods, two points must be considered concerning the results of the acidity measurements. First, the concentration of the
Scheme 1.1.

Figure 1.8. Complementarity of NMR methods in determining the variation of the acidity with the ionization of the indicator.\textsuperscript{46} Curve 1: line-shape analysis; curve 2: chemical shift measurement.
indicator cannot be neglected as in the UV method, especially when the BH$_2^{2+}$ is in low concentration. Second, aldehydes and ketones that have been generally used in the NMR methods are not true Hammett bases and the acidity that is derived should be considered only in a relative sense.

1.4.3. Electrochemical Methods

Electrochemistry provides a number of techniques for acidity measurements. The hydrogen electrode is the most reliable method in nonreducible solvents. It has been shown, however, that its reliability is limited to relatively weak acid solutions. A more general method was proposed by Strehlow and Wendt$^{47}$ in the early 1960s. They suggested a method to measure the potential variation of a pH-dependent system with respect to a reference system whose potential was solvent-independent. The measurement was made with a cell using Pt/H$_2$/H$_2$O–H$_2$SO$_4$, ferrocene–ferricinium (1:1)/Pt, containing sulfuric acid solution up to 100%. Strehlow defined an acidity function $R_0(H)$ [Eq. (1.32)], in which $E_x$ and $E_1$ are the electromotive forces of the cell at proton activities $x$ and unity, respectively.

$$R_0(H) = \frac{F}{2.303RT} E_x - E_1$$  \hspace{1cm} (1.32)

Like all the other acidity functions, $R_0(H)$ equals pH in dilute aqueous solution. In strong acids, this function should be a logarithmic measure of the proton activity as long as the normal potential of the redox system, ferrocene–ferricinium, is constant. This was, however, not the case in very strong acid solutions because ferrocene underwent protonation. Other electrochemical pH indicators have been proposed, such as quinine–hydroquinone or semiquinone–hydroquinone, the basicity of which can be modified by substitution on the aromatic ring. These electrochemical indicators have been used with success by Trémillon and co-workers$^{48}$ for acidity measurements in anhydrous HF and HF containing superacids.

In principle, the $R_0(H)$ function is of limited interest for kinetic applications because the indicators are chemically very different from the organic substrates generally used. On the other hand, as the measurements are based on pH determination, the length of the acidity scale is limited by the pK value of the solvents. However, very interesting electrochemical acidity studies have been performed in HF by Trémillon and co-workers, such as the acidity measurement in anhydrous HF solvent and the determination of the relative strength of various Lewis acids in the same solvent. By studying the variation of the potential of alkane redox couples as a function of acidity, the authors provide a rational explanation of hydrocarbon behavior in the superacid media.$^{48}$

1.4.4. Chemical Kinetics

The idea that the acidity function may be useful in determining the rates of acid-catalyzed reactions was the main reason for development of the method first proposed
by Hammett and Deyrup. The parallelism between reaction rate and $H_0$ was noticed by Hammett in the early phase of his studies. Especially when the protonation of the substrate parallels the protonation of the Hammett bases, the observed rate constant can be plotted versus $-H_0$ with unit slope. The validity of this principle for a large number of acid-catalyzed reactions and its limitation due to deviations in the protonation behavior has been reviewed extensively. This method has also been applied to obtain a qualitative classification of the relative acidity of various superacid solutions.

Brouwer and van Doorn used this approach in the early 1970s. In the NMR study of the interconversion rates of alkyl tetrahydrofuryl ions 7 and 8 (Scheme 1.2), proceeding via dicarbenium ion intermediates, they measured the overall rate of rearrangement in various superacid combinations of HF, HSO$_3$F, and SbF$_5$.

By making the assumption that the rates were only proportional to the concentration of the dication and taking into account the temperature dependence of the rate, they could estimate the relative acidity of these systems. By repeating these experiments with closely related reactions and varying the acid composition, they were able to estimate the relative acidity of 1:1 HF: SbF$_5$, 9:1 HF–SbF$_5$, 1:1 HSO$_3$F–SbF$_5$, and 5:1 HSO$_3$F–SbF$_5$ as $500:10^{-1}:10^{-5}$. These estimations have since been shown to be very approximate in comparison with the results obtained by other techniques. Moreover, rates can be affected by other factors than acidity such as solvation effects and temperature. Until now, however, no $H_0$ value has been measured for the 1:1 HF–SbF$_5$ medium.

The Friedel–Crafts acid systems HCl–AlCl$_3$ and HBr–AlBr$_3$ are widely used superacids of great practical significance, and various techniques have been used to rank Lewis acids such as AlCl$_3$ and AlBr$_3$ in strong Brønsted acids such as HSO$_3$F, CF$_3$SO$_2$H, HF, HBr, and HCl. However, despite opposite claims, their acidity is lower than those of the fluoroacids discussed.
1.4.5. Heats of Protonation of Weak Bases

Arnett\textsuperscript{54} had shown that several problems still exist in the currently available methods dealing with the behavior of weak bases in solution. For example, $pK_A$ values of a wide variety of carbonyl compounds given in the literature vary over an unacceptably wide range. The variations are due not only to the activity coefficient problems, but also to practical difficulties such as the effect of media on position of the UV absorption peaks.\textsuperscript{55} The previously discussed NMR method seems to alleviate these problems. An alternative method was proposed by Arnett and co-workers measuring the heats of protonation of number of weak bases in HSO$_3$F medium for which $pK_A$ values are known from other methods. They found a good correlation of these heats of protonation with recorded $pK_A$ values. The heat of protonation method has the advantage over the acidity function procedure that all measurements are made in the same solvent. These studies were applied to systems such as Magic Acid\textsuperscript{®} (HSO$_3$F–SbF$_5$) but not extended to HF-based superacids.

1.4.6. Theoretical Calculations and Superacidity in the Gas Phase

The knowledge of acidities or basicities independent from solvation effects is of general interest to chemists because it gives important information on the solvent effects. It also allows the study of the intrinsic ability of the chemical structure of the acid or base to stabilize the anion/cations involved in the acid–base reaction and a quantitative structure–property relationship. In the last two decades, with the development of techniques of high-pressure mass spectrometry,\textsuperscript{56} flowing afterglow,\textsuperscript{57} and ion cyclotron resonance,\textsuperscript{58} the study of ion–molecule reactions became possible in the gas phase. These techniques operating under very different conditions of pressure and time domain gave good agreement for the relative basicity measurements via proton transfer equilibria determination.

Extension of these studies in the superacid field has been reported,\textsuperscript{59} which proposes a quantitative intrinsic superacidity scale for sulfonic acids based on measurement of the proton transfer equilibrium between the superacid and its conjugate base. The free energies (and enthalpies) of deprotonation (kcal mol$^{-1}$) have been estimated (within ±2.5 kcal mol$^{-1}$) as follows: HPO$_3$ 303 (311); H$_2$SO$_4$ 302 (309); HSO$_3$F 300 (307); CF$_3$SO$_3$H 299 (306). These results show that the acidity order of the Brønsted superacids measured in the gas phase mirrors the acidity order found in solution. However, the method will be difficult to apply for measuring the large acidity domain of these acids when combined as usual with strong Lewis acids such as SbF$_5$.

Koppel et al.\textsuperscript{60} have established a series of overlapping values of relative gas-phase acidities of a large number of very strong CH, OH, and SH Brønsted acids by using the pulsed FT ion cyclotron resonance (ICR) equilibrium constant method. The new intrinsic acidity scale covers a wide range from (CF$_3$)$_2$NH ($\Delta G_{\text{acid}}$ = 324.3 kcal mol$^{-1}$) to (C$_4$F$_9$SO$_2$)$_2$NH ($\Delta G_{\text{acid}}$ = 284.1 kcal mol$^{-1}$) and is anchored to the thermodynamic $\Delta G_{\text{acid}}$ value (318.1 kcal mol$^{-1}$) of HBr. In several cases, the gas-phase acidity of compounds which make up the scale exceeds the acidity of such
traditionally strong mineral acids as HCl, HBr, HI, or H2SO4 by more than 30 powers of 10. Based on these results, the acid (C₄F₉SO₂)₂NH may be the strongest measured gas-phase superacid.

Subsequently, the development of both theoretical DFT methods and more sophisticated ab initio high-level MP2-type calculations has also spurred investigations in the superacid field.

Later, in another series of papers, Koppel et al. used a theoretical approach at the G2 or G2(MP2) level and also with the DFT method (B3LYP/6-311+G** level) to calculate the intrinsic acidities and gas-phase deprotonation enthalpies for 39 neutral strong or superstrong Brønsted acids, Brønsted–Lewis conjugate superacids, and even acidic cluster of zeolites. Comparison of the calculated gas-phase acidity with the H° values of the neat acid showed a fairly linear correlation. Similar DFT studies were carried out in calculating the Bronsted acidity of polycyanated hydrocarbons in the gas phase.

ΔG values of deprotonation are as low as 249–250 kcal mol⁻¹ for HSO₃⁻ or HF associated with SbF₅ or SO₃. The strongest superacid was found to be dodecafluorocarborane acid CB₁₁F₁₂H with a ΔG of 209 kcal mol⁻¹ even suggesting that the dodeca(trifluoromethyl)carborane acid CB₁₁(CF₃)₁₂H would be below the 200 kcal mol⁻¹ level!

Mota and co-workers have investigated the nature of superacid electrophilic species in HF–SbF₅ by density functional theory and measured the ability of the system to protonate light alkanes (methane, ethane, propane, and isobutane). More recently, Gutowski and Dixon have recalculated [G3(MP2) theory] the intrinsic gas-phase acidities of a series of 21 Brønsted acids. The computed results are in excellent agreement with experimental gas-phase acidities in the range 342–302 kcal mol⁻¹ to within < 1 kcal/mol for 14 out of 15 acids. However, acids with experimental acidities lower than 302 kcal mol⁻¹ were found to have large deviations compared to the G3(MP2) results.

1.4.7. Estimating the Strength of Lewis Acids

A quantitative method to determine the strength of Lewis acids and to establish similar scales as discussed in the case of Brønsted acids would be very useful. However, establishing such a scale is extremely difficult and challenging. Whereas the Brønsted acid–base interaction always involves proton transfer, which allows a meaningful quantitative comparison, no such common relationship exists in the Lewis acid–base interaction. The result is that the definition of strength has no real meaning with Lewis acids.

The “strength” or “coordinating power” of different Lewis acids can vary widely against different Lewis bases. Thus, for example, in the case of boron trihalides, boron trifluoride coordinates best with fluorides, but not with chlorides, bromides, or iodides. In coordination with Lewis bases such as amines and phosphines, BF₃ shows preference to the former (as determined by equilibrium constant measurements). The same set of bases behaves differently with the Ag⁺ ion. The Ag⁺ ion complexes phosphines much more strongly than amines. In the case of halides (F⁻, Cl⁻, Br⁻, and I⁻), fluoride is the most effective base in protic acid solution. However, the order
is reversed in the case of Ag⁺; iodide forms the most stable complex, whereas fluoride forms the least stable one.

The Lewis acidity with respect to strong bases such as NH₃ is greater for BCl₃ than for BF₃. In contrast, toward weak bases such as CO, BF₃ is a stronger acid than BCl₃.⁶⁷

Despite the apparent difficulties, a number of qualitative relationships were developed to categorize Lewis acids.

Pearson proposed a qualitative scheme in which a Lewis acid and base is characterized by two parameters, one of which is referred to as strength and the other is called softness. Thus, the equilibrium constant for a simple acid–base reaction would be a function of four parameters, two for each partner. Subsequently, Pearson introduced the hard and soft acids and bases (HSAB) principle⁶⁸,⁶⁹ to rationalize behavior and reactivity in a qualitative way. Hard acids correspond roughly in their behavior to class a acids as defined by Schwarzenbach⁷⁰ and Chatt.⁶⁶ They are characterized by small acceptor atoms that have outer electrons not easily excited and that bear considerable positive charge. Soft acids, which correspond to class b acids, have acceptor atoms with lower positive charge, large size, and easily excited outer electrons. Hard and soft bases are defined accordingly. Pearson’s HSAB principle states that hard acids prefer to bind to hard bases while soft acids prefer to bind to soft bases. The principle has proven useful in rationalizing and classifying a large number of chemical reactions involving acid–base interactions in a qualitative manner,⁷¹ but it gives no basis for a quantitative treatment.

There are many attempts made in the literature⁷²,⁷³ to rate qualitatively the activity of Lewis acid catalysts in Friedel–Crafts-type reactions. However, such ratings largely depend on the nature of the reaction for which the Lewis acid catalyst is employed.

The classification of Lewis superacids as those stronger than anhydrous aluminum trichloride is only arbitrary. Just as in the case of Gillespie’s classification of Brønsted superacids,¹⁸,¹⁹ it is important to recognize that acids stronger than conventional Lewis acid halides exist with increasingly unique properties. Again the obvious difficulty is that reported sequences of Lewis acid strengths were established against widely varying bases. Still in applications such as ionizing alkyl halides to their corresponding carbocations, in heterocations systems, catalytic activity, and so on, Lewis acid halides such as SbF₅, AsF₅, TaF₅, and NbF₅, clearly show exceptional ability far exceeding those of AlCl₃, BF₃, and other conventional Lewis acid halides. Moreover, these super Lewis acid halides also show remarkable coordinating ability to Brønsted acids such as HF, HSO₃F, and CF₃SO₃H, resulting in vastly enhanced acidity of the resulting conjugate acids.

The determination of the strength of the Lewis acids MFₙ has been carried out in various solvents using the conventional methods. Numerous techniques have been applied: conductivity measurements,⁷⁴–⁷⁹ cryoscopy,⁸⁰–⁸³ aromatic hydrocarbon extraction,⁵³,⁸⁴ solubility measurements,⁸⁵–⁸⁷ kinetic parameters determinations,⁵²,⁸⁸,⁸⁹ electroanalytical techniques (hydrogen electrode),⁹⁰–⁹₃ quinones systems as pH indicators,⁹⁴–⁹⁷ or other electrochemical systems,⁹₈,⁹⁹ IR,¹⁰⁰,¹⁰¹ and acidity function (Hₒ) determinations with UV–visible spectroscopy,⁸,⁹,¹₄,¹₉,¹₀₂–¹⁰⁵ or with NMR spectroscopy.¹₀⁻₂,₄₄⁻₄₆,₁₀₆–₁₀₈ Gas-phase measurements are also available.¹₀₉–¹₁¹ Comparison of the results obtained by different methods shows large discrepancies (Table 1.2).

\]

In hydrogen fluoride, the Lewis acid strength is in the following decreasing order: SbF\textsubscript{5} > AsF\textsubscript{5} > TaF\textsubscript{5} > BF\textsubscript{3} > NbF\textsubscript{5}.

As in all areas, the theoretical tools developed in the last decade was also used to address this question. A theoretical approach with the semiempirical MNDO method
combined with $^1$H NMR chemical shift measurements has also been used to compare the relative acidity of 18 Lewis acids complexing crotonaldehyde. However, this scale does not completely agree with the pF scale determined in HF solution by electrochemical titration (Figure 1.9).

More recently, a quantitative scale for Lewis acidity based on fluoride ion affinities was calculated using *ab initio* calculations at the MP2/B2 level of theory. Due to its high basicity and small size, the fluoride ion reacts essentially with all Lewis acids; thus the fluoride affinity (or reaction enthalpy) may be considered as a good measure for the strength of a Lewis acid. An abbreviated pF scale is given in Table 1.3. This scale was used recently by Christe and Dixon for estimating the stability of salts of complex fluoro anions and cations. The pF value represents the fluoride affinity in kcal mol$^{-1}$ divided by 10.

**1.4.8. Experimental Techniques Applied to Solid Acids**

Since solid acid catalysts are used extensively in chemical industry, particularly in the petroleum field, a reliable method for measuring the acidity of solids would be extremely useful. The main difficulty to start with is that the activity coefficients for solid species are unknown and thus no thermodynamic acidity function can be properly defined. On the other hand, because the solid by definition is heterogeneous, acidic and basic sites can coexist with variable strength. The surface area available for colorimetric determinations may have widely different acidic properties from the bulk material; this is especially true for well-structured solids like zeolites. It is also not possible to establish a true acid–base equilibrium.
Moreover, the accessibility of sites causes discrepancies in the different methods and to measure the acidity of solids. Because several reviews on this subject have been published in recent years, we will just illustrate this problem with sulfated zirconia (SZ), probably the most studied single catalyst in the last 20 years.

SZ was claimed to be a solid superacid by Hino and Arata in 1980 on the basis of its ability to isomerize \( n \)-butane at low temperature. Since then, various authors using all experimental techniques available tried to verify the superacidity character. Whereas the color change of Hammett indicators suggested a value of \(-14\) to \(-16\) on the \( H_0 \) scale, the use of these indicators is considered invalid for surface acidity measurements. The color change of the indicators used (in the \( pK_a \) range of \(-10\) to \(-16\)) is always from colorless to yellow; this makes the visual appreciation very subjective especially on catalysts, which are generally not colorless. Moreover, the change in color may be due to sites able to transfer electrons to the aromatic ring of the indicators, and also Brønsted and Lewis sites may both contribute.

On the basis of less subjective UV spectroscopy using the same indicators, Hall and co-workers concluded that neither SZ nor zeolites (such as HY, HZSM-5, and H-MOR) were superacids. However, on the basis of \( ^1H \) NMR spectroscopy and Raman spectroscopy, Knözinger and co-workers suggested that superacidic protons were present on SZ; but here again, chemical shifts that depend on various factors should not be directly related to acidity. Early EPR studies by Vedrine and co-workers have shown the formation of charge transfer complexes with benzene followed by the formation of radical cations. Since benzene has a high ionization potential, their observation was interpreted as being very probably due to strong Lewis acidity.

On the basis of its catalytic activity in isobutane conversion, this catalyst was described as zirconia-supported oleum, but this hypothesis implies that the reaction mechanism is known, which is not the case. On the same basis, Fraenkel suggested also that SZ was a very strong solid superacid.

In contrast, another \( ^1H \) NMR study suggested that the acidity was lower than that of zeolite HZSM-5. Using a combination of solid-state NMR and theoretical methods, the same authors concluded on the nonsuperacidic character for SZ. Similarly, CO adsorption experiments monitored by microcalorimetry and FT–IR concluded to a lower Brønsted acidity in comparison with H-zeolites and showed that acidity is comparable to that of sulfuric acid. On the basis of FT–IR analysis of adsorbed CO and acetonitrile, Sachtl and co-workers arrived at the same conclusion and suggested that the exceptional activity of SZ can be attributed to its ability to stabilize transition states on the surface. According to a recent diffuse reflectance IR study, SZ does not exhibit higher acid strength than zeolites.

Results of temperature-programmed desorption (TPD) of ammonia or argon were attributed to superacid sites. TPD of very weak bases such as substituted benzenes has been used successfully to compare the superacid character of a series
of sulfate-treated mixed oxides. However, the validity of TPD measurements and the results of IR study of adsorbed pyridine for acidity determinations have been questioned by various authors as nonspecific to the acid site, considering that different probes may probe different sites providing only qualitative information and measure only an overall acidity. In fact the question whether the alleged superacidity is related to Brønsted or Lewis acid sites is still debated.

More recently, the reactivity of SZ has been assigned to its oxidizing ability, which should not be surprising because it has often been considered as SO₃ adsorbed on zirconium oxide. However, that sulfated zirconia is not only an oxidant but also a strong protic acid has been demonstrated by Sommer, Walspurger, and co-workers on the basis H/D exchange experiments with neopentane.

Concerning the acidity of zeolites, Koltunov et al. have shown in a series of papers that reactions involving superelectrophiles could be achieved with excellent yields.

It appears that despite the lack of reliability of acidity determination of solid acids by spectroscopic means and in the absence of knowledge of the nature of the initial step in alkane activation by solid acids the qualification of superacid solids has been and continues to be used, despite the absence of a clear definition of solid superacidity.

Considering the impressive amount of literature on sulfated zirconia and solid superacids, it will be difficult to impose a definition a posteriori. On the other hand, due to the large difference in acidity and in structure between various liquid superacids, there is no unique chemistry of hydrocarbons in liquid superacids. For this reason it is not possible to suggest a unequivocal definition of solid superacidity at the present stage. Nevertheless, it seems clear from all the data presently available that at high temperatures the chemical reactivity of the proton bound to the surface shows a close resemblance to the one observed at low temperature in liquid superacidic media as will be seen in Chapter 5.

REFERENCES
As discussed in Chapter 1, superacids encompass both Brønsted and Lewis types and their conjugate combinations. In this chapter, we will review the physical and chemical properties of the most significant superacids. The development of high-field multinuclear NMR instrumentation as well as new tools facilitating theoretical approaches notably increased the level of our knowledge concerning the structure of superacids, particularly those associated with HF or HSO₃F.

2.1. PRIMARY SUPERACIDS

2.1.1. Brønsted Superacids

Using Gillespie’s arbitrary definition, Brønsted superacids are those whose acidity exceeds that of 100% sulfuric acid ($H_0 = -12$). The physical properties of the most commonly used Brønsted superacids are summarized in Table 2.1.

2.1.1.1. Perchloric Acid. Historically, it was Conant’s study of the protonating ability of weak bases (such as aldehydes and ketones) by perchloric acid that first called attention to the “superacid” behavior of certain acid systems.

Commercially, perchloric acid is manufactured either by reaction of alkali perchlorates with hydrochloric acid or by direct electrolytic oxidation of 0.5 N hydrochloric acid. Another commercially attractive method is by the direct electrolysis of chlorine gas ($Cl_2$) dissolved in cold dilute perchloric acid. Perchloric acid is commercially available in a concentration of 70% (by weight) in water, although 90% perchloric acid also had limited availability (due to its explosive hazard, it is no longer provided in this strength); 70–72% HClO₄, an azeotrope of 28.4% H₂O, 71.6% HClO₄, boiling at 203°C is safe for usual applications; however, because it is a strong oxidizing agent, it must be handled with care. Anhydrous acid (100% HClO₄) is prepared by vacuum distillation of the concentrated acid solution with a dehydrating agent such as Mg(ClO₄)₂. It is stable only at low temperatures for a few days, decomposing to give HClO₄·H₂O (84.6% acid) and ClO₂.
Perchloric acid is extremely hygroscopic and is a very powerful oxidizer. Contact of organic materials with anhydrous or concentrated perchloric acid can lead to violent explosions. For this reason, the application of perchloric acid has serious limitations. The acid strength, although not reported, can be estimated to be around $H_0 = -13$ for the anhydrous acid.

Formation of various perchlorate salts such as $\text{NO}_2^+\text{ClO}_4^-$, $\text{CH}_3\text{CO}^+\text{ClO}_4^-$, and $\text{R}^+\text{ClO}_4^-$, via ionization of their appropriate neutral precursors in perchloric acid can also lead to serious explosions. The probable reason is not necessarily the thermal instability of the ionic perchlorates but instead their equilibrium with highly unstable and explosive covalent perchlorates [Eqs. (2.1)–(2.3)].

$$
\begin{align*}
\text{NO}_2^+\text{ClO}_4^- & \rightleftharpoons \text{NO}_2\text{OClO}_3 & (2.1) \\
\text{CH}_3\text{CO}^+\text{ClO}_4^- & \rightleftharpoons \text{CH}_3\text{COOClO}_3 & (2.2) \\
\text{R}^+\text{ClO}_4^- & \rightleftharpoons \text{ROClO}_3 & (2.3)
\end{align*}
$$

Actually, no specific advantage exists in using perchlorate salts, when comparable safe conjugate fluoride salts such as $\text{BF}_4^-$, $\text{SbF}_6^-$, and $\text{Sb}_2\text{F}_{11}^-$ are available. The use of perchlorate salts always necessitates extreme care and precautions.

The chemistry of perchloric acid along with its applications has been well reviewed. The main use of perchloric acid has been the use of its salts (such as $\text{NH}_4^+\text{ClO}_4^-$) as powerful oxidants in pyrotechniques and rocket fuels.

### 2.1.1.2. Chlorosulfuric Acid

Chlorosulfuric acid, the monochloride of sulfuric acid, is a strong acid containing a relatively weak sulfur–chlorine bond. It can be prepared by the direct combination of sulfur trioxide and dry hydrogen chloride gas. The reaction is very exothermic and reversible, making it difficult to obtain chlorosulfuric acid free of $\text{SO}_3$ and $\text{HCl}$. Upon distillation, even in good vacuum, some

dissociation is unavoidable. The acid is a powerful sulfating and sulfonating agent as well as a strong dehydrating agent and a specialized chlorinating agent. Because of the above properties, chlorosulfuric acid is rarely used for its protonating superacid properties.

Gillespie and co-workers\textsuperscript{7,8} have measured systematically the acid strength of the H\textsubscript{2}SO\textsubscript{4}–CISO\textsubscript{3}H system using aromatic nitro compounds as indicators. They found an \( H_0 \) value of \(-13.8\) for 100% CISO\textsubscript{3}H.

An extensive review about the physical and chemical properties of chlorosulfuric acid and its use as a reagent is available.\textsuperscript{9}

2.1.1.3. Fluorosulfuric Acid. Fluorosulfuric acid, HSO\textsubscript{3}F, is a mobile colorless liquid that fumes in moist air and has a sharp odor. It may be regarded as a mixed anhydride of sulfuric acid and hydrogen fluoride. It has been known since 1892\textsuperscript{10} and is prepared commercially from SO\textsubscript{3} and HF in a stream of HSO\textsubscript{3}F. It is readily purified by distillation, although the last traces of SO\textsubscript{3} are difficult to remove. When water is excluded, it may be handled and stored in glass containers, but for safety reasons the container should always be cooled before opening because the gas pressure may have developed from hydrolysis [Eq. (2.4)]. Fluorosulfuric acid generally also contains hydrogen fluoride as an impurity, but according to Gillespie the hydrogen fluoride can be removed by repeated distillation under anhydrous conditions. The equilibrium in Eq. (2.5) always produces traces of SO\textsubscript{3} and HF in stored HSO\textsubscript{3}F samples. When kept in glass for a long time, SiF\textsubscript{4} and H\textsubscript{2}SiF\textsubscript{6} are also formed (secondary reactions due to HF).

\[
\begin{align*}
\text{HSO}_3\text{F} & + \text{H}_2\text{O} \rightleftharpoons \text{H}_2\text{SO}_4 + \text{HF} \quad (2.4) \\
\text{HSO}_3\text{F} & \rightleftharpoons \text{SO}_3 + \text{HF} \quad (2.5)
\end{align*}
\]

Fluorosulfuric acid is employed as a catalyst and chemical reagent in various chemical processes including alkylation, acylation, polymerization, sulfonation, isomerization, and production of organic fluorosulfates.\textsuperscript{11} It is insoluble in carbon disulfide, carbon tetrachloride, chloroform, and tetrachloroethane, but is soluble in nitrobenzene, diethyl ether, acetic acid, and ethyl acetate and it dissolves most organic compounds that are potential proton acceptors. The IR, Raman, and NMR spectra of fluorosulfuric acid have been reported.\textsuperscript{12,13} The \(^{19}\text{F}\) chemical shift is 44.9 ppm downfield from CCl\textsubscript{3}F.\textsuperscript{14} The acid can be dehydrated to give S\textsubscript{2}O\textsubscript{5}F\textsubscript{2}.\textsuperscript{15} Electrolysis of fluorosulfuric acid gives S\textsubscript{2}O\textsubscript{6}F\textsubscript{2} or SO\textsubscript{2}F\textsubscript{2} + F\textsubscript{2}O, depending on conditions employed.

HSO\textsubscript{3}F has a wide liquid range (mp = \(-89.0^\circ\text{C}\), bp = \(+162.7^\circ\text{C}\)), making it advantageous as a superacid solvent for the protonation of a wide variety of weak bases.

Fluorosulfuric acid ionizes in H\textsubscript{2}SO\textsubscript{4} according to Eq. (2.6). The \( H_0 \) acidity function has been measured by Gillespie and Peel\textsuperscript{8} for the H\textsubscript{2}SO\textsubscript{4}–HSO\textsubscript{3}F system using fluoro- and nitroaromatic bases. They found a strong increase in acidity in the vicinity of 100%
HSO₃F which can be attributed to the self-ionization of the acid [Eq. (2.7)].

\[
\begin{align*}
\text{HSO}_3\text{F} + \text{H}_2\text{SO}_4 & \rightleftharpoons \text{H}_3\text{SO}_4^+ + \text{SO}_3\text{F}^- \\
2 \text{HSO}_3\text{F} & \rightleftharpoons \text{H}_2\text{SO}_3\text{F}^+ + \text{SO}_3\text{F}^- 
\end{align*}
\]  

(2.6)  
(2.7)

The neat acid is ascribed an \(H_0\) value of \(-15.1\). This ranks it as the strongest known simple Brønsted acid. Trifluoromethanesulfonic acid (HSO₃CF₃), in which fluorine is replaced by a CF₃ group, has a slightly lower acid strength \((-14.1\)). HSO₃F, the most widely used superacidic solvent system, has a low viscosity and good thermal stability and wide liquid range \((\sim250^\circ\text{C from mp to bp})\). The acidity of HSO₃F can be increased further by the addition of Lewis acid fluorides \(\text{vide infra}\).

2.1.1.4. Perfluoroalkanesulfonic Acids. Perfluoroalkanesulfonic acids were first reported in 1956\(^\text{16}\) and subsequently have been prepared by electrochemical fluorination (ECF) of the corresponding alkanesulfonyl halides and subsequent hydrolysis\(^\text{17–19}\) [Eq. (2.8)]. The boiling points, density, and \(H_0\) values of these acids are compared in Table 2.2.

\[

\end{align*}
\]  

(2.8)

**Trifluoromethanesulfonic Acid.** Trifluoromethanesulfonic acid (CF₃SO₃H, triflic acid), the first member in the perfluoroalkanesulfonic acid series, has been studied extensively, and excellent reviews describing its physical and chemical properties have been published.\(^\text{18,19}\) Besides its preparation by electrochemical fluorination of methanesulfonyl halides,\(^\text{20}\) triflic acid may also be prepared from

\] (2.10)

In 2000, Rhodia began the production of triflic acid by a new process, which includes sulfination of potassium trifluoroacetate, oxidation of the resulting potassium triflinate, followed by acidification and purification\textsuperscript{23} [Eq. (2.11)].

\[
\begin{align*}

\end{align*}
\] (2.11)

CF\textsubscript{3}SO\textsubscript{3}H is a stable, hygroscopic liquid that fumes in moist air and readily forms the stable monohydrate (hydronium triflate), which is a solid at room temperature (mp 34°C, bp 96°C/1 mmHg). The \textsuperscript{19}F NMR chemical shift for the neat acid is 78.5 ppm upfield from CCl\textsubscript{3}F.\textsuperscript{24} Conductivity measurements\textsuperscript{25} in glacial acetic acid have shown triflic acid to be one of the strongest simple protic acids known, similar to HSO\textsubscript{3}F and HClO\textsubscript{4}. The acidity of the neat acid as measured by UV spectroscopy with a Hammett indicator shows indeed an $H_0$ value of $-14.1$.\textsuperscript{17} It is miscible with water in all proportions and soluble in many polar organic compounds such as dimethyl formamide, dimethyl sulfoxide, and acetonitrile. It is generally a very good solvent for organic compounds that are capable of acting as proton acceptors in the medium. The exceptional leaving group properties of the triflate anion (CF\textsubscript{3}SO\textsubscript{3}\textsuperscript{-}) makes triflate esters excellent alkylating agents. The acid and its conjugate base do not provide a source of fluoride ion, even in the presence of strong nucleophiles. Furthermore, because it lacks the sulfonating properties of oleums and HSO\textsubscript{3}F, it has gained a wide range of application as a catalyst in organic synthesis—for example, in Friedel–Crafts chemistry, protection group chemistry, the synthesis of heterocycles, carbohydrate chemistry, polymerization, and organometallic chemistry (see Chapter 5).

**Higher Perfluoroalkanesulfonic Acids.** Higher homologous perfluoroalkanesulfonic acids are hygroscopic, oily liquids or waxy solids. They are prepared by the distillation of their salts from H\textsubscript{2}SO\textsubscript{4}, giving stable hydrates that are difficult to dehydrate. The acids show the same polar solvent solubilities of trifluoromethanesulfonic acid but are quite insoluble in benzene, heptane, carbon tetrachloride, and perfluorinated liquids. Many of the perfluoroalkanesulfonic acids have been prepared by the electrochemical fluorination reaction\textsuperscript{20} (or conversion of the corresponding perfluoroalkane iodides to their sulfonyl halides). $\alpha,\omega$-Perfluoroalkanedisulfonic acids have been prepared by aqueous alkali permanganate oxidation of the compounds RSO\textsubscript{2}(CF\textsubscript{2}CF\textsubscript{2})\textsubscript{n}SO\textsubscript{2}R.\textsuperscript{26} C\textsubscript{8}F\textsubscript{17}SO\textsubscript{3}H and higher perfluoroalkanesulfonic acids are surface-active agents and form the basis for a number of commercial fluorochemical
surfactants. Because of toxicity problems perfluorooctanesulfonic acid is phased out, however, from Teflon manufacturing process.

**Extreme care should be taken while handling the perfluoroalkanesulfonic acids.** Studies suggest that extreme irritation and permanent eye damage could occur following eye contact, even if the eyes are flushed immediately with water. Acute inhalation toxicity studies (in albino rats) indicate that high vapor or mist concentrations can cause significant respiratory irritation. All contacts of the acids and their esters with the skin should be avoided. Usual procedures for treatment of strong acid burns should be applied.

Contact of the perfluoroalkanesulfonic acids with cork, rubber, cellulose, and plasticized materials will cause discoloration and deterioration of these materials. Samples are best stored in glass ampoules or glass bottles with Kel-F or Teflon plastic screw-cap linings.

Acidity measurements on perfluoroalkanesulfonic acids have been reported by Commeyras and co-workers (Table 2.2). All the acids show a strong UV absorption band around 283 nm. Up to C₄ chain length, the acids are liquids at room temperature, and the $H_0$ measurements using Hammett bases were carried out at 22°C. Perfluorohexanesulfonic acid C₆F₁₃SO₃H melts at 33°C and the $H_0$ value has been corrected for the temperature difference. Perfluorooctanesulfonic acid is a waxy solid melting at 90°C, and its acidity has not been measured. Surprisingly, there is relatively little decrease in acidity with increase in the perfluoroalkyl chain length, and the first CF₂ group adjacent to the sulfonic acid moiety is most responsible for the acid strength. Thus, even higher solid homologous members are capable of acting as superacidic catalysts. As will be seen in Section 2.2.2.6, the acidity of these acids can be further enhanced by complexation with Lewis acids such as SbF₅ and TaF₅.

Harmer et al. have reported the synthesis of 1,1,2,2-tetrafluoroethanesulfonic acid, CF₂HCF₂SO₃H, and 1,1,2,3,3,3-hexafluoropropanesulfonic acid, CF₃CFHCF₂SO₃H, by the addition of sulfite to fluorinated double bonds [Eq. (2.12)]. The product acids have lower volatility, which makes their handling easier, and are expected to have similar acidity values to those of their fully fluorinated counterparts. In fact, catalytic conversions of a range of transformations were found to be comparable to triflic acid (see Chapter 5).

\[ (2.12) \]

### 2.1.1.5. Hydrogen Fluoride

Anhydrous hydrogen fluoride is generally prepared by action of concentrated sulfuric acid on calcium fluoride “Fluorspar” (>98% CaF₂). The estimated world production is about 1 million tons mostly to
prepare chlorofluorocarbons and synthetic cyalite necessary for aluminum production. It is also used as catalyst for alkylation in the petrochemistry and for uranium processing UF₄/UF₆.

**Extreme caution should be used in handling anhydrous HF.** It can cause severe burns that may not be noticed immediately but will be very painful later; HF dehydrates the skin, and F⁻ removes Ca²⁺ from tissues and delays healing. Immediate thorough water washing of any exposed skin should be followed by application of calcium gluconate gel or benzalkonium chloride (trade name: Zephiran Chloride), and medical attention is essential.

Due to its highly corrosive nature, HF should be handled in plastic, Teflon, PTFE, or Monel apparatus. Due to strong hydrogen bonding, it forms a two-dimensional polymer in the liquid phase. It is also a useful solvent both for organic and inorganic compounds. Until the more recent work by Gillespie and Liang the H₀ value for the neat anhydrous acid (15.1) was generally underestimated (11) due to the very high sensitivity of the autoprotonation equilibrium to trace impurities of water [Eq. (2.13)]. Its association with SbF₅ generates the strongest superacid system (vide infra).

\[
2 \text{HF} \rightleftharpoons \text{H}_2\text{F}^+ + \text{F}^- \quad K = 10^{-10} \quad (2.13)
\]

An easier-to-handle, convenient liquid alternative of anhydrous hydrogen fluoride is pyridinium poly(hydrogen fluoride) (PPHF), also known as Olah’s reagent. The PPHF reagent (30 wt% pyridine–70 wt% HF), which is stable up to 50°C, is in equilibrium with a small amount of free hydrogen fluoride and, consequently, is the liquid equivalent of HF and serves as a general-purpose fluorinating agent. A similar solid polymeric reagent, poly-4-vinylpyridinium poly(hydrogen fluoride) (PVPHF), has also been developed.

Stable dialkyl ether poly(hydrogen fluoride) complexes (R₂O─[HF]ₙ, R = Me, Et, n-Pr) have recently been developed by Prakash, Olah, and colleagues. DFT calculations suggest a cyclic poly(hydrogen fluoride) bridged structure. Dimethyl ether–5 HF (DMEPHF) was shown to be a convenient and effective fluorinating agent (see Section 5.10.1).

### 2.1.1.6. Carborane Superacids H(CB₁₁HR₅X₆).

Recently, new carbon superacids, icosahedral carboranes H(CB₁₁HR₅X₆) (where X = chlorine, bromine or iodine; R = H, Me, Cl), have been described by Reed et al., whose conjugate base, the carborane anion (CB₁₁HR₅X₆)⁻, is quite inert due to low nucleophilicity.

As a nonoxidizing, low-nucleophilicity system, reaction of carborane acid H(CB₁₁H₆X₆) (Figure 2.1) with C₆₀ gives HC₆₀⁺ as a stable ion in solution. Arenium ions are also remarkably stable in this medium. Previously investigated only at subambient temperatures in highly superacidic media, protonated benzene is readily isolated as a crystalline salt, thermally stable to >150°C. Solid-state ¹³C NMR spectra are similar to those observed earlier in solution, indicating that lattice
interactions are comparable to solution solvation effects.\textsuperscript{35,36} A new and cheap synthesis of the [\textit{closo}-\textit{CB}_{11}\text{H}_{12}]^{-} anion, which serves as a starting material for the preparation of many extremely weakly nucleophilic anions, has been reported by Michl and co-workers.\textsuperscript{37}

2.1.2. Lewis Superacids

In Chapter 1, we arbitrarily defined Lewis superacids as those that are stronger than anhydrous aluminum chloride in their reactivity, the most commonly used Friedel–Crafts catalyst. Of course, Lewis acidity is only a relative term concerning specific bases and involved counterions (association, steric hindrance, etc.). The physical properties of some of the Lewis superacids are given in Table 2.3.

2.1.2.1. Antimony Pentafluoride. Antimony pentafluoride (SbF\textsubscript{5}) is a highly associated, colorless, very viscous liquid at room temperature. It is hygroscopic and fumes in moist air. Its viscosity at 20°C is 460 cP, which is close to that of glycerol. The pure liquid can be handled and distilled in glass if moisture is excluded. Commercial antimony pentafluoride is shipped in steel cylinders or in perfluoroethylene bottles for laboratory quantities.

\begin{table}
\centering
\caption{Physical Properties of Some Lewis Superacids}
\begin{tabular}{lcccr}
\hline
 & SbF\textsubscript{5} & AsF\textsubscript{5} & TaF\textsubscript{5} & NbF\textsubscript{5} \\
\hline

Boiling point, °C & 142.7\textsuperscript{a} & −52.8 & 229 & 236 \\
Specific gravity (15°C), g cm\textsuperscript{-3} & 3.145 & 2.33\textsuperscript{b} & 3.9 & 2.7 \\
\hline
\end{tabular}
\end{table}

\textsuperscript{a}Anomalous high value because of association of molecules.
\textsuperscript{b}At the bp.
The polymeric structure of the liquid SbF$_5$ has been established by $^{19}$F NMR spectroscopy and is shown to have the frameworks depicted in Figure 2.2. A cis-fluorine bridged structure is found in which each antimony atom is surrounded by six fluorine atoms in an octahedral arrangement.

*Ab initio* molecular dynamics were used to investigate the structure of liquid SbF$_5$. The results confirm the high tendency of SbF$_5$ to oligomerize and impart a highly ionic character to the Sb–F bond. It confirms also the cis-bridged chain polymer as the most stable structure.

Antimony pentafluoride is also a powerful oxidizing and an effective fluorinating agent. It is even able to oxidize small alkanes below room temperature. It readily forms stable intercalation compounds with graphite (*vide infra*), and it spontaneously inflames phosphorus and sodium. It coordinates or associates with water to form SbF$_5$·2 H$_2$O, an unusually stable solid hydrate (probably a hydronium salt, H$_3$O$^+$SbF$_5$OH$^-$) that reacts violently with excess water to form a clear solution. Slow hydrolysis can be achieved in the presence of dilute NaOH and forms Sb(OH)$_6$.$\cdot$H$_2$O.

Sulfur dioxide and nitrogen dioxide form 1:1 adducts, SbF$_5$–SO$_2$ and SbF$_5$–NO$_2$, respectively, as do practically all nonbonded electron pair donor compounds. The exceptional ability of SbF$_5$ to complex and subsequently ionize nonbonded electron pair donors (such as halides, alcohols, ethers, sulfides, amines, etc.) to carbocations, recognized first by Olah (Chapter 3), has made it one of the most widely used Lewis halides in the study of cationic intermediates and catalytic reactions.

Vapor density measurements suggest a molecular association corresponding to (SbF$_5$)$_3$ at 150°C and (SbF$_5$)$_2$ at 250°C. On cooling, SbF$_5$ gives a nonionic solid composed of trigonal bipyramidal molecules. Antimony pentafluoride is prepared by the direct fluorination of antimony metal or antimony trifluoride (SbF$_3$). It can also be prepared by the reaction of SbCl$_5$ with anhydrous HF, but the exchange of the fifth chloride is difficult and the product is generally SbF$_4$Cl.$\cdot$SbF$_5$. As shown by conductometric, cryoscopic, and related acidity measurements, it appears that antimony pentafluoride is by far the strongest Lewis acid known in the condensed phase. Thus, it is preferentially used in preparing stable ions and conjugate superacids (*vide infra*). Antimony pentafluoride is also a strong oxidizing agent, allowing, for example, preparation of arene dications. At the same time, its easy reducibility to antimony trifluoride represents a limitation in many applications, although it can be refluorinated.
2.1.2.2. Arsenic Pentafluoride. Arsenic pentafluoride (AsF$_5$) is a colorless gas at room temperature, condensing to a yellow liquid at $-53^\circ$C. Vapor density measurements indicate some degree of association, but it is a monomeric covalent compound with a high degree of coordinating ability. It is prepared by reacting fluorine with arsenic metal or arsenic trifluoride. As a strong Lewis acid fluoride, it is used in the preparation of ionic complexes and in conjunction with Brønsted acids forms conjugate superacids. It also forms with graphite stable intercalation compounds that show electrical conductivity comparable to that of copper. Great care should be exercised in handling any arsenic compound because of potential high toxicity.

2.1.2.3. Phosphorus Pentafluoride. Phosphorus pentafluoride, which may be prepared by fluorinating phosphorus pentachloride with AsF$_3$ or CaF$_2$, is a colorless gas (bp $-93^\circ$C) that reacts with Lewis bases to form a six-coordinated anion [Eq. (2.14)]. However in HF, PF$_5$ is a non-electrolyte and hexafluorophosphoric acid HPF$_6$ is available as a 60% solution in water (which cannot be considered a superacid). In the $pF^{-}$ scale established by Christe to measure the strength of Lewis acids on the basis of fluoride affinity (see Section 1.4.7) it is rated 9.49, lower than AsF$_5$(10.59) but higher than BF$_3$(8.31).

$$\text{PF}_5 + \text{F}^- \rightarrow \text{PF}_6^- \quad (2.14)$$

2.1.2.4. Tantalum and Niobium Pentafluoride. The close similarity of the atomic and ionic radii of niobium and tantalum are reflected by similar properties of tantalum and niobium pentafluorides. They are thermally stable white solids that may be prepared either by the direct fluorination of the corresponding metals or by reacting the metal pentachlorides with HF. Surprisingly, even reacting metals with HF gives the corresponding pentafluorides. They both are strong Lewis acids complexing a wide variety of donors such as ethers, sulfides, amines, halides, and so on. They both coordinate with fluoride ion to form anions of the type (MF$_6$)$^{-}$. TaF$_5$ is a somewhat stronger acid than NbF$_5$ as shown by acidity measurements in HF. The solubility of TaF$_5$ and NbF$_5$ in HF and HSO$_3$F is much more limited than that of SbF$_5$ or other Lewis acid fluorides, restricting their use to some extent. At the same time, their high redox potentials and more limited volatility make them catalysts of choice in certain hydrocarbon conversions, particularly in combination with solid catalysts. Their chemistry has been extensively reviewed.

2.1.2.5. Boron Trifluoride. BF$_3$ is a pungent colorless gas (bp $-99.9^\circ$C) that can be prepared by reacting B$_2$O$_3$ or borates with CaF$_2$ and concentrated H$_2$SO$_4$. A modern two-stage process gives a much better yield [Eq. (2.15)]. It is a strong Lewis acid that forms adducts with most compounds having an available electron lone pair. Unlike other boron halides, BF$_3$ does not undergo hydrolysis with water under usual conditions to boric acid and HF. Moreover, because it is a volatile gas, it can be easily recovered for reuse.
It is commonly available as diethyl etherate \((\text{C}_2\text{H}_5)_2\text{O}-\text{BF}_3\) and is widely used as catalyst in Friedel–Crafts and other acid-catalyzed reactions in organic chemistry.\(^{49}\)

Prakash, Olah, and co-workers have explored the use of boron trifluoride monohydrate \((\text{BF}_3-\text{H}_2\text{O})\) and the complex \(\text{BF}_3-2\text{CF}_3\text{CH}_2\text{OH}\) in acid-catalyzed transformations. Both \(\text{BF}_3-\text{H}_2\text{O}\) and \(\text{BF}_3-2\text{CF}_3\text{CH}_2\text{OH}\) are strong acids and very efficient superacidic catalysts comparable in acid strength to at least that of 100% sulfuric acid.\(^{50–52}\) The structure of the \(\text{BF}_3-2\text{CF}_3\text{CH}_2\text{OH}\) adduct has been studied using multinuclear NMR spectroscopy and DFT calculations (Figure 2.3). The activity of both complexes was successfully tested on various acid-catalyzed organic reactions (see Chapter 5).

2.1.2.6. **Tris(pentafluorophenyl) Borane.** \(\text{B(C}_6\text{F}_5)_3\) was first prepared by Stone, Massey, and Park in 1963 by treatment of pentafluorophenyllithium with \(\text{BCl}_3\) at low temperature\(^{53,54}\) [Eq. (2.16)]. Since the lithium reagent may eliminate \(\text{LiF}\) explosively, the use of the Grignard reagent, pentafluorophenylmagnesium bromide, is a safer alternative. It is thermally robust, resistant toward oxidation by molecular oxygen, and water-tolerant. It is best known for its role as activator in Ziegler–Natta chemistry. However, its special properties as a strong Lewis acid are increasingly used in organic and organometallic chemistry.\(^{55,56}\) Its Lewis acidity, determined by the NMR method developed by Childs,\(^{57}\) is described as between that of \(\text{BF}_3\) and \(\text{BCl}_3.\(^{58}\)

\[
\text{C}_6\text{F}_5\text{Br} + n\text{-BuLi} \xrightarrow{\text{pentane}} \text{C}_6\text{F}_5\text{Li} \xrightarrow{	ext{BCl}_3} \text{B(C}_6\text{F}_5)_3
\]

Another related boron Lewis superacid, \(\text{B(CF}_3)_3\), is worth mentioning, even though it has not been isolated.\(^{59}\) However, the corresponding anion \(\text{B(CF}_3)_4^-\) is known and

![Figure 2.3. Geometrical parameters by DFT calculations of the BF₃–2CF₃CH₂OH complex.](image-url)
found in simple salts (Ag, Li, K, etc.). $\text{B(CF}_3\text{)}_4^{-}$ has been shown to be weakly coordinating as determined by examining the stability of $\text{[Ag(CO)}_x\text{][B(CF}_3\text{)}_4^{-}]$ ($x = 1 – 4$) complexes generated from $\text{Ag[B(CF}_3\text{)}_4]$ and CO.$^{60}$ Furthermore, the complex $\text{B(CF}_3\text{)}_3\text{CO}$ in hydrogen fluoride is considered to be a strong conjugate Bronsted–Lewis superacid furnishing the weakly coordinating $\text{[(CF}_3\text{)}_3\text{BF]}^{-}$ anion in the generation of homoleptic metal carbonyl complexes.$^{59}$ (see Section 4.5.1).

### 2.1.2.7. Boron Tris(trifluoromethanesulfonate).

Boron tris(trifluoromethanesulfonate) [boron tris(triflate), $\text{B(OSO}_2\text{CF}_3\text{)}_3$, $\text{B(OTf)}_3$] was first prepared by Olah and co-workers from boron chloride and bromide.$^{61}$ [Eq. (2.17)]. Boron tris(triflate) is a volatile, colorless, extremely hygroscopic liquid (mp 43–45°C, bp 68–73°C/0.5 torr), which distills in vacuum without decomposition. It is readily soluble in such solvents as $\text{CH}_2\text{Cl}_2$, Freon-113, $\text{SO}_2$, and $\text{SO}_2\text{ClF}$. Data for acidity measurement are not available; but on the basis of its catalytic activity in Friedel–Crafts reactions (see Section 5.2.3) and the ability to generate stable, long-lived carbocations in $\text{SO}_2\text{ClF}$ solution at low temperature, $\text{B(OSO}_2\text{CF}_3\text{)}_3$ is a super Lewis acid.

$$\text{BX}_3 + 3 \text{CF}_3\text{SO}_3\text{H} \quad \xrightarrow{} \quad \text{B(OSO}_2\text{CF}_3\text{)}_3 + 3 \text{HX}$$

($X = \text{Br, Cl}$)  

### 2.1.2.8. Aprotic Organic Superacids (Vol’pin’s Systems).

In the late 1980s, Vol’pin and his group$^{62}$ noticed the high activity of complexes of acyl halides with aluminum halides toward low-temperature transformation of alkanes and cycloalkanes. They proposed to call these media Aprotic Organic Superacids (AOS).$^{63}$ The activity necessitated 2 moles of aluminum halide per mole of acyl halide. Multinuclear NMR studies showed that the 1:1 complexes give exclusively donor–acceptor complexes in solution, whereas the 2:1 complexes form equilibrium mixtures of acylium salts [Eq. (2.18)]. Later on, they also included systems such as $\text{CHBr}_3$–$2\text{AlBr}_3$ and $\text{CCl}_4$–$2\text{AlBr}_3$, which were very active at room temperature for alkane isomerization, cracking, and various functionalizations$^{62,64}$ (see Chapter 5).

$$\text{RCOX} + 2 \text{AlX}_3 \quad \xrightarrow{} \quad \text{RCOX} \quad \xrightarrow{} \quad \text{Al}_2\text{X}_6 \quad \xrightarrow{} \quad \text{CH}_2\text{X}_2 \quad \xrightarrow{} \quad \text{RCO}^{+}\text{Al}_2\text{X}_7^-$$

($R = \text{alkyl, aryl}$  

($X = \text{Br, Cl}$)  

The key of alkane transformation was assigned to the formation of $\text{CX}_3^{+}$-type cations that are electrophilic enough (probably due to a second complexation of $\text{AlX}_3$), to abstract a hydride anion from linear and cycloalkanes. When these cations are generated in superacidic media, a protosolvation induces a superelectrophilic character, which was supported by Olah on the basis of high-level $\text{ab initio}$ calculations.$^{65}$ The generation of these cations was also used by various teams$^{66,67}$ to initiate selective low temperature alkane activation.
2.2. BINARY SUPERACIDS

2.2.1. Binary Brønsted Superacids

2.2.1.1. Hydrogen Fluoride–Fluorosulfuric Acid. Fluorosulfuric acid containing up to 5% of HF acting as a protic coacid was found to be very efficient for isomerization of \( n \)-butane to isobutane at room temperature, whereas pure \( \text{HSO}_3\text{F} \) did not show this activity. Moreover, at higher HF concentration the activity diminishes substantially.\(^{68}\)

2.2.1.2. Hydrogen Fluoride–Trifluoromethanesulfonic Acid. The acidity of this binary Brønsted acid system has not been measured, but the superacidic properties are mentioned in numerous patents concerning fluorination, olefin alkylation, and hydrocarbon conversion.

2.2.1.3. Tetra(Hydrogen Sulfato)Boric Acid–Sulfuric Acid. \( \text{HB(HSO}_4\text{)}_4 \) prepared by treating boric acid, \( \text{B(OH)}_3 \), with sulfuric acid ionizes in sulfuric acid as shown by acidity measurements\(^7\) [Eq. (2.19)].

\[
\text{HB(HSO}_4\text{)}_4 + \text{H}_2\text{SO}_4 \rightleftharpoons \text{H}_3\text{SO}_4^+ + \text{B(HSO}_4\text{)}_4^- \quad (2.19)
\]

The increase in acidity is, however, limited to \( H_0 = -13.6 \) as a result of insoluble complexes that precipitate when the concentration of the boric acid approaches 30 mol%. Figure 2.4 shows the composition-related acidity increase for the system in comparison with oleum.

2.2.2. Conjugate Brønsted–Lewis Superacids

2.2.2.1. Oleums–Polysulfuric Acids. \( \text{SO}_3 \)-containing sulfuric acid (oleum) has been long considered as very strong mineral acid and one of the earliest superacid systems to be recognized. The concentration of \( \text{SO}_3 \), in sulfuric acid can be determined by weight or by electrical conductivity measurement.\(^{69}\) The vapor pressure of oleum rises rapidly with the increase in concentration of \( \text{SO}_3 \) and increase in temperature\(^ {70}\) as shown in Figure 2.5.

Lewis and Bigeleisen,\(^{71}\) who first determined the Hammett acidity function values for oleums, used a method to derive them from the vapor pressure measurements. Brand et al.,\(^{72}\) however, subsequently by the use of nitro compound indicators showed that the \( H_0 \) values are not directly related to the vapor pressure. The most accurate \( H_0 \) values for oleums so far have been published by Gillespie et al.\(^7\) (Table 2.4).

The increase in acidity on addition of \( \text{SO}_3 \) to sulfuric acid is substantial, and an \( H_0 \) value of \(-14.5\) is reached with 50 mol% \( \text{SO}_3 \). The main component up to this \( \text{SO}_3 \) concentration is pyrosulfuric (or disulfuric) acid \( \text{H}_2\text{S}_2\text{O}_7 \). Upon heating or in the
Figure 2.4. $H_0$ acidity function values for $\text{H}_2\text{SO}_4$–$\text{HB(SO}_4\text{H)}_4$ and $\text{H}_2\text{SO}_4$–$\text{SO}_3$.\(^7\)

Figure 2.5. Vapor pressure of oleum.
presence of water, it decomposes and behaves like a mixture of sulfuric acid and sulfur trioxide. In sulfuric acid, it ionizes as a stronger acid \([\text{Eq. (2.20)}]\).

\[
\begin{align*}
\text{H}_2\text{S}_2\text{O}_7 + \text{H}_2\text{SO}_4 & \rightleftharpoons \text{H}_3\text{SO}_4^+ + \text{HS}_2\text{O}_7^- \\
K &= 1.4 \times 10^{-2}
\end{align*}
\]

At higher SO\(_3\) concentration, a series of higher polysulfuric acids such as H\(_2\)S\(_3\)O\(_{10}\), H\(_2\)S\(_4\)O\(_{13}\), and so on, are formed and a corresponding increase in acidity occurs. However, as can be seen from Table 2.4, the acidity increase is very small after reaching 50 mol% of SO\(_3\) and no data are available beyond 75%.

Despite its high acidity, oleum has found little application as a superacid catalyst, mainly because of its strong oxidizing power. Also, its high melting point and viscosity have considerably hampered its use for spectroscopic study of ionic intermediates and in synthesis, except as an oxidizing or sulfonating agent.

### 2.2.2.2. Fluorosulfuric Acid–Antimony Pentafluoride (“Magic Acid”).

Of all the superacids, a mixture of fluorosulfuric acid and antimony pentafluoride, named by Olah as “Magic Acid,” is probably the most thoroughly investigated concerning measurements of acidity and also the most widely used medium for the spectroscopic observation of stable carbocations (see Chapter 3). The fluorosulfuric acid–antimony pentafluoride system was developed in the early 1960s by Olah for the study of stable carbocations and was studied by Gillespie for the generation of electron-deficient inorganic cations. The name Magic Acid originated in Olah’s laboratory at Case Western Reserve University in the winter of 1966. The HSO\(_3\)F–SbF\(_5\) mixture was extensively used in his group to generate stable carbocations. J. Lukas, a German postdoctoral fellow, put a small piece of Christmas candle left over from a lab party into the acid system and found that it dissolved readily. He then ran an \(^1\)H NMR spectrum of the solution. To everybody’s amazement, he obtained a sharp spectrum of the tert-butyl cation. The long-chain paraffin, of which the candle is made, had obviously undergone extensive cleavage and isomerization to the more stable tertiary ion. It impressed Lukas and others in the laboratory so much that they started to nickname the acid system Magic Acid. The name stuck and soon others started to use it too. It is now a registered trade name and has found its way into the chemical literature.

The acidity of the Magic Acid system as a function of SbF\(_5\) content has been measured successively by Gillespie,\(^8\) Gold,\(^73\) Sommer,\(^74\) and their co-workers. The increase in acidity is very sharp at low SbF\(_5\) concentration and was estimated to

continue up to the value of $-27$ for the 90 mol% SbF$_5$ solution as shown in Figure 2.6.$^8,73–75$ This estimation was, however, questioned on the basis of the contrasting results obtained by various authors using different experimental techniques.$^{76}$ It seems that a value of $H_0 = -22$ to $-23$ is probably a fair estimation of the upper acidity limit of this most classic superacid system (Figure 2.7).

The initial ionization of HSO$_3$F–SbF$_5$ is shown in Eq. (2.21). At higher concentrations of SbF$_5$, larger polyantimony fluorosulfate ions are formed [Eq. (2.22)].

$$2 \text{HSO}_3\text{F} + \text{SbF}_5 \rightarrow \text{H}_2\text{SO}_3\text{F}^+ + \text{SbF}_5(\text{SO}_3\text{F})^- \quad (2.21)$$

$$\text{SbF}_5 + \text{SbF}_5(\text{SO}_3\text{F})^- \rightarrow \text{Sb}_2\text{F}_{10}(\text{SO}_3\text{F})^- \quad (2.22)$$

Due to these equilibria, which have been discussed by several authors,$^{77,78}$ the composition of the HSO$_3$F–SbF$_5$ system is quite complex and depends on the SbF$_5$ content. The first $^{19}$F NMR study by Commeyras and co-workers$^{14}$ has shown such dependence and is presented in Figure 2.8 for the major structural components, which are depicted in Table 2.5.

Free SbF$_5$ is not observed as it complexes the Brønsted acid and leads to its initial ionization [Eqs. (2.23) and (2.24)].

$$\text{HSO}_3\text{F} + \text{SbF}_5 \rightarrow \text{HFSO}_3\text{SbF}_5 \quad (2.23)$$
Figure 2.7. Dependence of $H_0$ acidity function values for the HSO$_3$F–SbF$_5$ system [ref. 8 (○) and ref. 76 (◊)].

Figure 2.8. Variation of the composition of HSO$_3$F–SbF$_5$, depending on SbF$_5$ content.$^{14}$
An interesting point in this system is that HSO$_3$F is completely ionized at 55% SbF$_5$ indicating that the SbF$_5$ binds preferentially to the acid instead of increasing the size of the anions.

Aubke and co-workers$^{79–81}$ reinvestigated the “Magic Acid” system by modern $500$ MHz $^1$H and $471$ MHz $^{19}$F NMR methods varying the molar fractions of SbF$_5$ in HSO$_3$F from 0.01 to 0.49 in the absence of diluents such as SO$_2$ or SO$_3$ClF. Using NMR tubes fitted with Teflon lining, the formation of HF and H$_2$O via interaction
with glass was avoided. In this concentration range, after keeping the samples for several months, only six anionic species were found besides SO$_3$$^-$: B$_1$, F, J, I, E, G (Table 2.5). As suggested earlier, the main species at the 1:1 concentration is B$_1$.

The major reason for the wide application of this superacid system compared with others (besides its very high acidity) is probably the large temperature range in which it can be used. In the liquid state, NMR spectra have been recorded from temperatures as low as $-160$°C (acid diluted with SO$_2$F$_2$ and SO$_2$CIF) and up to $+80$°C (neat acid in sealed NMR glass tube). Glass is attacked by the acid very slowly, when moisture is excluded. The Magic Acid system can also be an oxidizing agent that results in reduction to antimony trifluoride and sulfur dioxide. On occasion, this represents a limitation.

2.2.2.3. **Fluorosulfuric Acid–Sulfur Trioxide.** Freezing point and conductivity measurements show that SO$_3$ behaves as a nonelectrolyte in HSO$_3$F. Acidity measurements show a small increase in acidity that is attributed to the formation of fluoropolysulfuric acids HS$_2$O$_6$F and HS$_3$O$_9$F up to HS$_7$O$_{21}$F. Evidence for the existence of these acids has been obtained by $^{19}$F NMR measurements in SO$_2$CIF solutions at $-100$°C. The acidity of these solutions reaches a maximum of $-15.52$ on the $H_0$ scale for 4 mol% SO$_3$ and does not increase any further (Figure 2.9).

2.2.2.4. **HSO$_3$F–MF$_n$(SO$_3$F)$_{5-n}$; n = 3, 4, M = Nb, Ta.** Superacids based on the conjugation of HSO$_3$F with niobium and tantalum fluorosulfates acting as Lewis acids were also studied by Aubke and co-workers. In contrast with NbF$_5$ and TaF$_5$, these fluorosulfate Lewis acids are soluble in HSO$_3$F over a large concentration range. Results obtained by UV spectroscopy of dissolved Hammett bases seem to indicate

![Figure 2.9. $H_0$ acidity function values of the HSO$_3$F solvent system.](image)
that these systems are even more acidic than Magic Acids at low concentration (Figure 2.10).

2.2.2.5. Fluorosulfuric Acid–Arsenic Pentafluoride. $\text{AsF}_5$ ionizes in $\text{HSO}_3\text{F}$. The $\text{AsF}_5\text{SO}_3^-$ anion has the octahedral structure as shown for the antimony analog ($\text{B}_1$, Table 2.5). Values for the $H_0$ acidity function up to 4 mol% $\text{AsF}_5$ show a larger increase as compared with $\text{SO}_3$ (Figure 2.9) but smaller when compared with $\text{SbF}_5$.  

2.2.2.6. Perfluoroalkanesulfonic Acid-Based Systems. $C_n\text{F}_{n+1}\text{SO}_3\text{H–SbF}_5$. $\text{CF}_3\text{SO}_3\text{H–SbF}_5$ ($n = 1$) was introduced by Olah as an effective superacid catalyst for isomerizations and alkylations. The composition and acidity of systems where $n = 1, 2, 4$ have been thoroughly studied by Commeyras and co-workers. The $^{19}\text{F}$ NMR spectra are very similar for all of these systems and closely resemble those obtained with fluorosulfuric acid, as described in Section 2.2.2.6. The change in composition of the triflic acid–antimony pentafluoride system depending on the $\text{SbF}_5$ content has been studied. For the 1:1 composition, the main counteranion is $[\text{CF}_3\text{SO}_3\text{SbF}_5]^-$ and for the 1:2 composition $[\text{CF}_3\text{SO}_3(\text{Sb}_2\text{F}_{11})]^-$ is predominant, with the structures proposed for the anions shown in Figure 2.10. With increasing $\text{SbF}_5$ concentration, the anionic species grow larger and anions containing up to 5 $\text{SbF}_5$ units have been found (Figure 2.11). Under no circumstances was free $\text{SbF}_5$ detected.

It has not been possible to measure the acidity of the $\text{CF}_3\text{SO}_3\text{H–SbF}_5$ system by spectrophotometry because of its very strong absorption in the UV–visible spectrum. In comparison with the strength of the related perfluoroalkanesulfonic acids, its acidity should be very close or slightly higher (by 1 $H_0$ unit) than the acidity of the perfluoroethane- and perfluorobutanesulfonic acid–SbF$_5$ mixtures, which was
measured by Commeyras and co-workers\textsuperscript{14} (Figure 2.12). Because these authors were using the same spectroscopic technique as previously used by Gillespie, the measurements were limited to $H_0 = -18.5$ due to lack of suitable weak indicator bases. However, on the basis of $^{19}$F NMR structural studies, a moderate increase in acidity is expected beyond the 50 mol\% SbF\textsubscript{5} concentration corresponding to the autoprotolysis

![Figure 2.11. Components of the CF\textsubscript{3}SO\textsubscript{3}H–SbF\textsubscript{5} acid system.](image)

![Figure 2.12. $H_0$ acidity function values for various perfluoroalkanesulfonic acid-based systems.](image)
equilibrium [Eq. (2.25)].

\[
2 \text{HRF}_2\text{SO}_3\text{SbF}_5 \rightleftharpoons \text{RF}_3\text{SO}_3(\text{SbF}_5)^- + \text{H}_2\text{RF}_2\text{SO}_3\text{SbF}_5^+ \quad (2.25)
\]

\(\text{CF}_3\text{SO}_3\text{H} - \text{B(OSO}_2\text{CF}_3)^3\) \text{.} The acidity of triflic acid can also be substantially increased by addition of boron triflate \(\text{B(OSO}_2\text{CF}_3)^3\) as indicated by Engelbrecht and Tschager\(^8^4\) (Figure 2.12). The increase in acidity is explained by the ionization equilibrium [Eq. (2.26)]. Consequently, the triflic acid–boron tris(triflate) (triflatoboric acid) system may also be formulated as \(\text{CF}_3\text{SO}_3\text{H}^+ - \text{B(OSO}_2\text{CF}_3)^4^–\) or \((\text{CF}_3\text{SO}_3\text{H})_2 - \text{B(OSO}_2\text{CF}_3)^3\). The acid may also be prepared from boron trichloride and triflic acid [Eq. (2.27)].

\[
\text{B(OSO}_2\text{CF}_3)^3 + 2 \text{CF}_3\text{SO}_3\text{H} \rightleftharpoons \text{CF}_3\text{SO}_3\text{H}^+ + \text{B(OSO}_2\text{CF}_3)^4^- \quad (2.26)
\]

\[
4 \text{CF}_3\text{SO}_3\text{H} + \text{BCl}_3 \rightarrow -3\text{HCl} \quad \text{CF}_3\text{SO}_3\text{H} - \text{B(OSO}_2\text{CF}_3)^3 \quad (2.27)
\]

Acidity measurements were again limited for the lack of suitable indicator base and even 1,3,5-trinitrobenzene, the weakest base used, was fully protonated \((H_0 \approx -18.5)\) in the 22 mol% solution of boron triflate. Extrapolation of this system to 40% \(\text{B(CF}_3\text{SO}_3)^3\) in \(\text{CF}_3\text{SO}_3\text{H}\) would lead to an \(H_0\) value of \(-20\) in the Hammett scale. Consequently, the acidity is comparable to that of the ternary system \(\text{HSO}_3\text{F} - \text{SbF}_5 - \text{SO}_3\).

### 2.2.2.7. Hydrogen Fluoride–Antimony Pentafluoride (Fluoroantimonic Acid)

The \(\text{HF} - \text{SbF}_5\) (fluoroantimonic acid) system is considered the strongest liquid superacid and also the one that has the widest acidity range. Due to the excellent solvent properties of hydrogen fluoride, \(\text{HF} - \text{SbF}_5\) is used advantageously for a variety of catalytic and synthetic applications\(^8^5\) (see Chapter 5). Anhydrous hydrogen fluoride is an excellent solvent for organic compounds with a wide liquid range. Antimony pentafluoride ionizes anhydrous HF and the proton is solvated by the medium according to [Eq. (2.28)]

\[
2 \text{SbF}_5 + 2 \text{HF} \rightleftharpoons \text{H}_2\text{F}^+ + \text{SbF}_6^{-} (\text{Sb}_2\text{F}_{11}^-) \quad (2.28)
\]

Due to the small autoprotolysis constant \((K_{ap} \sim 10–12)\), the \(H_0\) value of neat anhydrous HF was difficult to measure. Trace amount of impurities increased the \(H_0\) value by several orders of magnitude, and for this reason the value of \(H_0 = -11\) was generally found in the literature. In 1987, Gillespie and Liang\(^3^0\) used a set of nitroaromatic indicators and found that the \(H_0\) value of anhydrous HF was \(-15.1\), in good agreement with the prediction of Devynck\(^8^6\) based on the electrochemical method (see Section 1.4.3). Figure 2.13 shows the dramatic change in acidity of anhydrous HF when 1 mol base or 1 mol acid is added.
Considering the fact that the $H_0$ values of neat anhydrous HF and pure HSO$_3$F are the same ($\sim -15.1$), it is interesting to notice the much higher sensitivity of HF to SbF$_5$ addition: A 1 $M$ solution of HF–SbF$_5$ is about 104 times stronger acid than a 1 $M$ solution of SbF$_5$ in HSO$_3$F. In order to reach an $H_0$ value of $-21$, 25 times more SbF$_5$ has to be added to HSO$_3$F than to HF (Figure 2.14).

![Figure 2.13. Comparison of calculated (full line) and experimental (squares) $-H_0$ values for the KF–HF–SbF system.](image)

**Figure 2.13.** Comparison of calculated (full line) and experimental (squares) $-H_0$ values for the KF–HF–SbF system.

![Figure 2.14. Comparison of $H_0$ acidity function values for HF–SbF$_5$ (ref. 74) and HSO$_3$F–SbF$_5$ (ref. 8).](image)

**Figure 2.14.** Comparison of $H_0$ acidity function values for HF–SbF$_5$ (ref. 74) and HSO$_3$F–SbF$_5$ (ref. 8).
Nevertheless, the acidity measurements based on the use of the benzhydryl cation indicator family show that the upper acidity limit of the HF–SbF5 system is reached with 10 mol% of SbF5. The weakest indicator available is protonated 4,4'-dimethoxybenzhydryl cation ($K_{BH^+} \approx -23$) and could not be further protonated, even in the most concentrated HF–SbF5 solutions.

Since the first quantitative study by Kilpatrick and Lewis, the ionic composition of the strongest superacid system, HF–SbF5, has been investigated by various analytical techniques. The results obtained from conductometric, cryoscopy, and vapor-phase measurements, as well as infrared and $^{19}$F NMR spectroscopy, all agree that SbF5 is fully ionized in dilute HF solutions, first yielding the SbF6 anion. With increasing concentration of SbF5, increasing amounts of polymeric SbF5 and increasing amounts of polymeric anions (Sb2F11, Sb3F16, etc.) are formed.

On the basis of IR studies, Bonnet and Masherpa concluded that HF-solvated $H_3F_2^+$ was the predominant species in the range 0–20 mol% SbF5 followed by $H_3F_2^+$ in the 20–40 mol% range, replaced progressively by $H_2F^+$ above 40 mol% SbF5. $^{19}$F NMR studies show, however, that the proton exchange between the different cations $H_{n+1}F_{n}^+$ is very fast and it appears that the proton is always solvated to a maximum.

The HF–SbF5 system has also been reinvestigated by high-field NMR spectroscopy as well as by the theoretical methods such as $ab initio$ molecular dynamics and DFT theory.

The anionic composition of the HF–SbF5 system is less complex than the Magic Acid system because it comprises only $F^-$ (SbF5)$_n$ adducts with 1 < n < 4. It is interesting to note that, in contrast with sulfonic acid based systems, SbF5 prefers complexing fluoroantimonate ions instead of ionizing HF over the whole concentration range. In both HSO$_3$F- and CF$_3$SO$_3$H-based superacids, complete ionization of the acids was observed when the concentration of SbF5 reached 50 mol%. In contrast, in the HF–SbF5 system the $^{19}$F NMR signal of the unionized HF can be observed up to 80 mol% SbF5.

On the other hand, above 20 mol% SbF5, a small but increasing amount of unionized SbF5 can be observed, which may rationalize the change in the mechanism of alkane activation from the protolytic to the oxidative pathway, when the concentration of SbF5 increases over 20 mol% (see Section 5.1.1).

The anionic composition of the HF-SbF5 system as a function of SbF5 concentration is shown in Figure 2.15.

The structure of the anions has already been suggested by Dean and Gillespie in 1969 on the basis of 94.1 MHz $^{19}$F NMR spectral analysis and the structure of Sb$_2$F$_{11}^-$ has been confirmed by X-ray structural analysis (Figure 2.16).

The cationic species—that is, solvation of proton by HF—has also been the subject of various theoretical approaches in association with the development of the superacid field.

Kim and Klein have investigated SbF5 in liquid HF by $ab initio$ molecular dynamics simulation. They observed the formation of SbF$_6^-$ ion and a very fast diffusion of the proton along the hydrogen-bonded HF chains. The cationic species is the protonated HF chain, in good agreement with experimental results.
Esteves et al.\textsuperscript{97} have carried out a high-level [B3LYP/6-31++G**+RECP(Sb)] density functional study of the HF–SbF\textsubscript{5} system (Figure 2.17).

**2.2.2.8. Hydrogen Fluoride–Phosphorus Pentafluoride.** In the early 1960s, Clifford and Kongpricha\textsuperscript{102} measured the thermodynamic solubility constant of PF\textsubscript{6}– in HF and concluded that in contrast with BF\textsubscript{3}, PF\textsubscript{5} was a strong acid in HF. $H_0$ measurements in sulfolane solution showed HPF\textsubscript{6} to be a stronger acid than HClO\textsubscript{4}

![Figure 2.15](image). The anionic composition of the HF–SbF\textsubscript{5} system. (\textbullet) SbF\textsubscript{6}–; (\textsquare) Sb\textsubscript{2}F\textsubscript{11}–; (\textblacksquare) Sb\textsubscript{3}F\textsubscript{16}–; (\textasterisk) Sb\textsubscript{4}F\textsubscript{21}–; (\textcircled{\textbullet}) SbF\textsubscript{5}.\textsuperscript{87}

![Figure 2.16](image). Structure of the Sb\textsubscript{2}F\textsubscript{11}– anion.
and HSO$_3$F. However, the more recent theoretical calculations based on $ab$ initio methods at the G-31 G** level seem to indicate that the adduct HF–PF$_5$ is only weakly bound (note the long HF–F bond distance, Figure 2.18) and the PF$_5$ moiety is only weakly distorted and not prone to exchange its fluorine atom with HF.

### 2.2.2.9. Hydrogen Fluoride–Tantalum Pentafluoride.
HF–TaF$_5$ is a catalyst for various hydrocarbon conversions of practical importance. In contrast to antimony pentafluoride, tantalum pentafluoride is stable in a reducing environment. The HF–TaF$_5$ superacid system has attracted attention mainly through the studies concerning alkane–alkene alkylation and aromatic protonation. Generally, heterogeneous mixtures such as the 10:1 and 30:1 HF–TaF$_5$ have been used because of the low solubility of TaF$_5$ in HF (0.9% at 19°C and 0.6% at 0°C). For this reason, acidity measurements have been limited to very dilute solutions, and an $H_0$ value of $-$18.85 has been found for the 0.6% solution. Both electrochemical studies$^{106,107}$ and aromatic protonation studies$^{108}$ indicate that the HF–TaF$_5$ system is a weaker superacid compared to HF–SbF$_5$.

### 2.2.2.10. Hydrogen Fluoride–Boron Trifluoride (Tetrafluoroboric Acid).
Boron trifluoride ionizes in anhydrous HF [Eq. (2.29)]. The stoichiometric compound

$$
P - F^c = 1.532 - 1.541 \text{ Å}$$

$$
P - F^b = 1.568 \text{ Å}$$

$$
< F^a PF^b = 91.0^\circ$$

$$
< F^a PF^c = 116.8 - 117.0^\circ$$

$$
< \text{HFP} = 105.4^\circ$$

Figure 2.18. Calculated geometrical parameters of HF–PF$_5$. 

Figure 2.17. Geometrical parameters by DFT calculations of the $H_3F^+_2 Sb_2F_{11}^-$ and $H_2F^+ Sb_2F_{11}^-$ complex.
exists only in excess of HF or in the presence of suitable proton acceptors. The HF–BF$_3$ (fluoroboric acid)-catalyzed reactions cover many of the Friedel–Crafts-type reactions. One of the main advantages of this system is the high stability of HF and BF$_3$. Both are gases at room temperature and are easily recovered from the reaction mixtures.

$$\text{BF}_3 + 2 \text{HF} \rightleftharpoons \text{BF}_4^- + \text{H}_2\text{F}^+ \quad (2.29)$$

The large number of patents in this field demonstrates the industrial interest in this superacid system (such as isomerization of xylenes and carbonylation of toluene). The HF–BF$_3$ system in the presence of hydrogen has also been found to be an effective catalyst for ionic hydrodepolymerization of coal to liquid hydrocarbons. The basicity of many aromatic hydrocarbons has been measured in the HF–BF$_3$ system by NMR and vapor pressure determinations. Acidity measurements of the system have been limited to electrochemical determinations, and a 7 mol% BF$_3$ solution was found to have an acidity of $H_0 = -16.6$. This indicates that BF$_3$ is a much weaker Lewis acid as compared with either SbF$_5$ or TaF$_5$. Nevertheless, the HF–BF$_3$ system is strong enough to protonate many weak bases and is an efficient and widely used catalyst.

An ab initio study of BF$_3$ + (HF)$_n$ clusters has shown that up to $n = 3$, only weakly bonded van de Waals associations are found but with $n = 4–7$, cyclic clusters were formed in which BF$_3$ is hydrogen bonded to HF with 3 fluorine atoms. Microwave studies and IR investigations show that the intermolecular BF bond is nevertheless somewhat shorter than expected on the basis of pure van de Waals interactions.

### 2.2.2.11. Conjugate Friedel–Crafts Acids (HX–AlX$_3$, etc.)

The most widely used Friedel–Crafts catalyst systems are HCl–AlCl$_3$ and HBr–AlBr$_3$. These systems are indeed superacids by the present definition. However, experiments directed toward preparation from aluminum halides and hydrogen halides of the composition HAlX$_4$ were unsuccessful in providing evidence that such conjugate acids are not formed in the absence of proton acceptor bases.

The hydrogen chloride–aluminum chloride system has been investigated by Brown and Pearsall under a variety of conditions, including temperatures as low as $-120\,^\circ\text{C}$ by vapor pressure measurements. No evidence was found for a combination of the two components.

The catalytic activity of hydrogen bromide itself has been recognized for alkylation, acylation, and polymerization reactions. The experimental difficulty associated with its narrow liquid range is probably the reason why there is no acidity measurements available for neat HBr. $H_0$ measurements on a 1 M solution in anhydrous sulfolane have shown the following sequence of decreasing acidity: HBF$_4$ > HClO$_4$ > HSO$_3$F > HBr > H$_2$SO$_4$ > HCl. This sequence is in accord with conductometric measurements performed in glacial acetic acid by Gramstad. Gold and co-workers have shown that HBr in CF$_2$Br$_2$ is capable of protonating a variety of ketones and alcohols at sufficiently low temperatures ($-90\,^\circ\text{C}$ and
below) at which the conjugate acids can be observed by NMR under slow-exchange conditions.

This indicates that the acidity of HBr is between −10 and −13 on the $H_0$ scale. The acidity can be increased further by addition of a Lewis acid such as TaF$_5$ or AlBr$_3$. The relative acidity of the Lewis acids in HBr has been found to be in the order AlBr$_3$ > GaBr$_3$ > TaF$_5$ > BBr$_3$ > BF$_3$, a sequence deduced from selectivity parameter measurements in 2 $M$ solution, assuming an ideal behavior of the individual components. An advantage of HBr as a Brønsted acid is its nonoxidizing nature, but at the same time the bromide ion is a strong nucleophile and neat HBr is a very poor solvent for most of the organic substrates.

Aluminum bromide is sparingly soluble in HBr (1.77 g mol$^{-1}$ at −80°C), but its solubility increases substantially in the presence of aromatic or aliphatic hydrocarbons. In this case, two phases separate—the upper layer is pure HBr and the lower layer consists of a sludge, for which the following composition has been found$^{108}$: (R$^+$Al$_2$Br$_7$)$^-$–AlBr$_3$–HBr in the ratio 1 : 0.8 : 0.7. The commonly encountered sludges or “red oil” in Friedel–Crafts hydrocarbon conversion processes can thus be considered as a solution of carbocations in superacidic HBr–AlBr$_3$ and HCl–AlCl$_3$ systems. These systems are generally very complex, containing organic oligomers and alkylates. In the ethylation of benzene with the HCl–AlCl$_3$ system, the sludge was shown by NMR spectroscopy to contain the heptaethylbenzenium ion. Protonation studies based on $^{13}$C NMR chemical-shift measurements have shown that the HBr–AlBr$_3$ system is capable of protonating benzene at 0°C. Comparing these results with those obtained using HF–TaF$_5$, Făraşcu et al.$^{108}$ claimed that HBr–AlBr$_3$ was an acid of comparable strength to HF–SbF$_5$, a ranking also proposed by Kramer based on his selectivity parameter.$^{121}$ It is, however, highly unlikely that HBr–AlBr$_3$ has strength comparable to that of HF–SbF$_5$ because it is incapable of protonating many weak bases or ionizing precursors to long-lived carbocations (such as alkyl cations). An extensive discussion of Friedel–Crafts superacids is available and will not be repeated here.$^{109}$

2.3. TERNARY SUPERACIDS

2.3.1. HSO$_3$F–HF–SbF$_5$

When Magic Acid is prepared from fluorosulfuric acid not carefully distilled (which always contains about 2–5% of HF), upon addition of SbF$_5$ the ternary superacid system HSO$_3$F–HF–SbF$_5$ is formed.$^{123,124}$ Because HF is a weaker Brønsted acid, it ionizes fluorosulfuric acid, which, upon addition of SbF$_5$, results in a high-acidity superacid system at low SbF$_5$ concentrations. $^{19}$F NMR studies on the system have indicated the presence of SbF$_6$$^-$ and Sb$_2$F$_{11}$$^-$ anions, although these can result from the disproportionation of SbF$_5$(FSO$_3$)$^-$ and Sb$_2$F$_{11}$(FSO$_3$)$^-$. The ternary HSO$_3$F–HF–SbF$_5$ system was recognized as a highly efficient superacid catalyst in its own right by McCaulay in octane upgrading of light naphtha streams exhibiting improved selectivity and lifetime.$^{125}$
2.3.2. **HSO\textsubscript{3}F–HF–CF\textsubscript{3}SO\textsubscript{3}H**

As mentioned in Section 2.3.1, fluorosulfuric acid used in common laboratory practice always contains HF. A mixture of HSO\textsubscript{3}F and CF\textsubscript{3}SO\textsubscript{3}H is, in fact, the ternary superacid HSO\textsubscript{3}F–HF–CF\textsubscript{3}SO\textsubscript{3}H.

2.3.3. **CF\textsubscript{3}SO\textsubscript{3}H–HF–Lewis Acid**

Olah has applied liquid ternary catalysts comprising triflic acid, HF, and a Lewis acid (BF\textsubscript{3}, PF\textsubscript{5}, AsF\textsubscript{5}, SbF\textsubscript{5}, TaF\textsubscript{5}, NbF\textsubscript{5}) to upgrade natural gas liquids containing saturated straight-chain hydrocarbons to highly branched hydrocarbons (gasoline upgrading).

2.3.4. **HSO\textsubscript{3}F–SbF\textsubscript{5}–SO\textsubscript{3}**

When sulfur trioxide is added to a solution of SbF\textsubscript{5} in HSO\textsubscript{3}F, there is a marked increase in conductivity that continues until approximately 3 moles of SO\textsubscript{3} have been added per mole of SbF\textsubscript{5}. This increase in conductivity has been attributed to an increase in H\textsubscript{2}SO\textsubscript{3}F\textsuperscript{+} concentration arising from the formation of a much stronger acid than Magic Acid. Acidity measurements have confirmed the increase in acidity with SO\textsubscript{3}–SbF\textsubscript{5} in the HSO\textsubscript{3}F system (Figure 2.9). This has been attributed to the presence of a series of acids of the type H[SbF\textsubscript{5}(SO\textsubscript{3}F)] (see Table 2.5, anion F), H[SbF\textsubscript{3}(SO\textsubscript{3}F)\textsubscript{3}], H[SbF\textsubscript{2}(SO\textsubscript{3}F)\textsubscript{4}] of increasing acidity. Thus, of all the fluorosulfuric acid-based superacid systems, sulfur trioxide-containing acid mixtures are, however, difficult to handle and cause extensive oxidative side reactions when contacted with organic compounds.

2.4. **SOLID SUPERACIDS**

Considering the exceptional activity of liquid superacids and their wide application in hydrocarbon chemistry, it is not surprising that work was also extended to solid superacids. The search for solid superacids has become an active area since the early 1970s, as reflected primarily by the existence of extensive patent literature.

Solid acid catalysts such as mixed oxides (chalcides) have been used extensively for many years in the petroleum industry and organic synthesis. Their main advantage compared with liquid acid catalysts is the ease of separation from the reaction mixture, which allows continuous operation, as well as regeneration and reutilization of the catalyst. Furthermore, the heterogeneous solid catalysts can lead to high selectivity or specific activity. Due to the heterogeneity of solid superacids, accurate acidity measurements are difficult to carry out and to interpret. Up until now, the most useful way to estimate the acidity of a solid catalyst is to test its catalytic activity in well-known acid-catalyzed reactions.

Solid acidic oxide catalysts generally do not show intrinsic acidity comparable with liquid superacids, and therefore generally high temperatures are required to achieve catalytic activity.
Various solid acids were qualified in the literature as superacids on the basis of very different arguments. The most studied “solid superacid,” sulfated zirconia, and related sulfated oxides were considered as superacids because of their ability to convert \( n \)-butane into isobutane at low temperatures.

In the late 1990s, a series of reviews have been devoted to sulfated zirconia and its potential application in industry.\(^{128-134}\)

Zeolites such as HZSM-5 were considered as superacids on the basis of the initial product distribution in accord with C–H and C–C bond protolysis when isoalkanes were reacted at 500°C (the Haag and Dessau mechanism).\(^{135}\) The reactivity was assigned to superacidic sites in the zeolite framework.\(^{136}\) The superacid character of other solid acids was claimed on the basis of Hammett indicator color change\(^ {137,138}\) or on the basis of UV spectrophotometric measurements.\(^ {139,140}\) In 2000, a special issue of Microporous and Mesoporous Materials\(^ {141}\) was devoted to the superacid-type hydrocarbon chemistry taking place on solid acids as suggested by the late Werner Haag.

As already pointed out earlier (see Section 1.4.8), a clear definition of solid superacidity is needed. On the other hand, for catalysts to be able to activate alkanes at low temperatures, such as sulfated zirconias and heteropoly acids, the redox properties should not be neglected in the activation step.\(^ {142,143}\)

Nevertheless, a large number of solid acids may be considered as solid superacids on the basis of their ability to convert saturated hydrocarbons at moderate to low temperatures.

Moreover, recently the application of zeolites in organic synthesis demonstrated their ability to achieve reactions necessitating usually superelectrophilic intermediates as in superacid media.\(^ {144}\) These results cannot be rationalized on the basis of the acidic character alone and needs the understanding of confinement effects\(^ {145}\) in which case the zeolite cage behaves like a nanosized reactor favoring the contact between reactant and specific acidic sites. The electrostatic effects may also be important.

The following subchapters cover various solid superacids, including perfluorinated sulfonic acid resins (Nafion resins). Furthermore, in the past, various attempts have been made to obtain solid superacids by either (a) enhancing the intrinsic acidity of a solid acid by treatment with a suitable co-acid or (b) physically or chemically binding a liquid superacid to an otherwise inert surface. We will briefly review some of these attempts because most of these catalysts rapidly lose activity and need to be regenerated.

### 2.4.1. Zeolitic Acids

Zeolites are a well-defined class of crystalline, naturally occurring or synthetic aluminosilicates. They have a three-dimensional structure arising from a framework of \([\text{SiO}_4]^{4-}\) and \([\text{AlO}_4]^{5-}\) tetrahedra linked by their corners of shared oxygens. The frameworks are generally very open and contain channels and cavities in which cations and water molecules are located. The alkali cations have a high degree of mobility and can be easily exchanged, and the water molecule can be lost and regained the origin of their chemical properties.
Whereas the synthesis of zeolite occurs in nature and in the laboratory under strongly basic conditions (pH 9–11), they are widely used as catalysts in hydrocarbon chemistry under their acidic form. In order to obtain acidic zeolites, the alkali cations (K, Li, Na, Ca, etc.) are first exchanged by $\text{NH}_4^+$ followed by heating which, after release of ammonia, leaves the proton loosely attached to the framework on the Si–O–Al bridging group (Figure 2.19).

Quantifying precisely the acidity of zeolites or other acidic solids is a goal, which up to now has not been satisfactorily achieved. The main problem is the lack of an acceptable scale of solid acidity comparable to $pK_a$ scale for aqueous solutions or proton affinities for gas-phase reactions. For this reason all available physical and theoretical methods of investigation have been applied over the years on this subject and a large number of papers have been published. Several reviews are available.

Whereas the number of Brønsted acid sites can be easily determined, their acidity may vary depending on their position in the framework and also by interaction with Lewis acid sites. For these reasons and despite the various techniques tested, there are no general and reliable methods to measure the acidity of solid acids. The synthesis of active acidic zeolites used in industry still relies on a very empirical base, the most important character being their catalytic activity.

### 2.4.2. Polymeric Resin Sulfonic Acids

#### 2.4.2.1. Lewis Acid-Complexed Sulfonic Acid Resins.

In most of the acidic ion exchangers, the active sites are the sulfonic acid groups that are attached to a solid backbone such as sulfonated coal, sulfonated phenol–formaldehyde resins, or sulfonated styrene–divinylbenzene cross-linked polymers. The latter sulfonated resins are the only type acidic enough to gain importance as a catalyst for acid-catalyzed electrophilic reactions. The most widely used are the Dowex 50 (Dow Chemicals) and Amberlite IR-120 (Rohm and Haas)-type resins, which are made by sulfonation of cross-linked polystyrene–divinylbenzene beads. Dowex 50 is comparable in acid strength to HCl and therefore is considered as a solid acid of moderate strength.

The acidity of these resins, however, increases significantly by treating them with Lewis acid halides. Gates and co-workers have prepared a superacid catalyst from AlCl$_3$ and beads of macroporous, sulfonated polystyrene–divinylbenzene. The
catalyst was prepared by exposing the macroporous beads of the polymeric Brønsted acid at 110°C to a stream of nitrogen containing sublimed AlCl₃. HCl was liberated and the resulting polymer had an S:Al:Cl ratio of 2:1:2. Electron microprobe X-ray analysis has shown that Al and Cl were uniformly dispersed throughout each polymer bead. By analogy with the known structure of liquid superacids, structure 1 was suggested [Eq. (2.30)]. This AlCl₃-complexed polystyrenesulfonic acid resin catalyst was found to be capable of isomerizing and cracking n-hexane at 85°C in a flow reactor with an overall initial conversion of 80%.

![Chemical Structure](image)

(2.30)

### 2.4.2.2. Perfluorinated Polymer Resin Acids.

A convenient solid perfluorinated sulfonic acid can be readily generated from DuPont’s commercially available potassium salts of Nafion brand ion membrane resins (a copolymer of perfluorinated epoxide and vinylsulfonic acid, Figure 2.20). Nafion-H-catalyzed reactions gained substantial interest and are reviewed in Chapter 5. Similarly, C₈ to C₁₈ perfluorinated sulfonic acids, such as perfluorodecanesulfonic acid [CF₃(CF₂)₉SO₃H, PDSA], are very strong acids and are useful catalysts for many organic syntheses.

Nafion membrane materials were originally developed for electrochemical applications. The acid strength (−H₀) is estimated to be between 11 and 13; that is, the acidity of Nafion is comparable to that of concentrated sulfuric acid. In these systems, the sulfonic acid group is attached to a CF₂ or CF group in a perfluorinated backbone.

![Chemical Structure](image)

Figure 2.20. The structure of Nafion resin.
This structure provides high acidity sites, and at the same time the perfluorinated polymer itself is highly inert and resists acid cleavage. The maximum operating temperature in continuous operation is 175°C; however, Nafion can be used at even higher temperature in aqueous systems and proton-donating organic solvents. Nafion is a noncorrosive solid marketed as the potassium salt in the form of granules (beads).

Other perfluorinated ionomer membranes, chemically very similar to Nafion, are also available commercially. Aciplex, manufactured by the Asahi Chemical Company, is very similar to Nafion, except that it has perfluoropropanesulfonic acid side chains. Flemion (Asahi Glass Company), in contrast, possesses perfluorobutanoic acid functions.

Two significant drawbacks of Nafion-H in catalytic applications are its very low surface area (0.02 m² g⁻¹) and the hindered accessibility of the active sites (sulfonic acid groups) located inside the pockets of the polymeric backbone. Consequently, the specific activity of Nafion, namely, the number of reacting molecules per unit weight, is extremely low.

To overcome these difficulties, Harmer and co-workers have used the in-situ sol–gel technique to develop Nafion–silica nanocomposite solid acid catalysts. During the process, nanometer-size silica particles are formed, which are aggregated to produce a porous silica network entrapping the Nafion particles. The nanocomposites have large surface areas (typically 150–500 m² g⁻¹)—that is, approximately four orders of magnitude larger than that of the starting Nafion polymer resin with Nafion particles having a typical particle size in the range 2–20 nm. Synthesis conditions, particularly the choice of the silica source, allow us to tailor the microstructure, surface area, and acidity of the nanocomposites. Furthermore, Nafion loading can also be varied easily up to about 40 wt%. Another method, repeated impregnation of spinodal porous silica with aqueous methanol solution of Aciplex resin, has also been used to prepare Aciplex–SiO₂ samples. Furthermore, Nafion was also embedded into ordered mesoporous MCM-41 silica material.

The high acidity of the unique sulfonic acid function of Nafion can also be utilized by tethering perfluoroalkanesulfonic acid groups to the surface of various silicas. Two approaches have been described to prepare such hybrid organic–inorganic materials. The grafted materials have been prepared by reacting preformed silica materials (MCM-41, SBA-15) with sultone 2 [Eq. (2.31)]. Co-condensation of tetraethoxy-silane with 4 in the presence of dodecylamine template, in turn, furnished the HMS-based material 5 [Eq. (2.32)].

The new Nafion-nanocomposite catalysts are produced by DuPont and marketed as Nafion SAC materials with Nafion loading between 10% and 20%. Additional information for perfluorinated sulfonic acid resin nanocomposites including characterization by a variety of physical and chemical methods can be found in a recent review paper.168

2.4.3. Enhanced Acidity Solids

The acidic sites of solid acids may be of either the Brønsted (proton donor, often OH group) or Lewis type (electron acceptor). Both types have been identified by IR studies of solid surfaces using the pyridine adsorption method. The absorption band at 1460 cm\(^{-1}\) is assigned to pyridine coordinated with the Lewis acid site, and another absorption at 1540 cm\(^{-1}\) is attributed to the pyridinium ion resulting from the protonation of pyridine by the Brønsted acid sites. Various solids displaying acidic properties, whose acidities can be enhanced to the superacidity range, are listed in Table 2.6.

The natural clay minerals are hydrous aluminum silicates with iron or magnesium replacing aluminum wholly or in part, and with alkali or alkaline earth metals present as essential constituents in some others. Their acidic properties and natural abundance have favored their use as catalysts for cracking of heavy petroleum fractions. With the exception of zeolites and some specially treated mixed oxides for which superacid properties have been claimed, the acidity as measured by the color changes of absorbed Hammett bases is generally far below the superacidity range. They are inactive for alkane isomerization and cracking below 100 °C and need co-acids to reach superacidity.

2.4.3.1. Brønsted Acid-Modified Metal Oxides: TiO\(_2\)–H\(_2\)SO\(_4\); ZrO\(_2\)–H\(_2\)SO\(_4\). By exposing freshly prepared Ti(OH)\(_4\) to 1 N sulfuric acid followed by calcination in air at 500 °C for 3 h, Hino and Arata\(^{137}\) have obtained a solid catalyst active for isomerization of butane in low yields at room temperature. The acid strength as indicated by the color change of a Hammett indicator (2,4-dinitrobenzene) was found to be as high as \(H_0 = -14.5\).

Subsequently, the same authors\(^{138}\) described the preparation of a solid superacid catalyst with acid strength of \(H_0 = -16\) with a sulfuric acid-treated zirconium oxide. They exposed Zr(OH)\(_4\) to 1 N sulfuric acid and calcined it in air at approximately 600 °C. The obtained catalyst was able to isomerize (and crack) butane at room temperature. The acidity was examined by the color change method using Hammett indicators added to a powdered sample placed in sulfuryl chloride. The
existence of both Brønsted and Lewis sites was shown by the IR spectra of absorbed pyridine.

The X-ray photoelectron and IR spectra showed that the catalyst possessed bidentate sulfate ion coordinated to the metal. The specific surface areas were much larger than those of the zirconium oxides, which had not undergone the sulfate treatment. The interesting feature of these catalysts is the high temperature at which they are prepared, which means that they maintain their acidity at temperatures as high as 500°C and should thus be easy to regenerate and reuse.

Considering the high activity obtained after treatment of these oxides with H₂SO₄, it is rather surprising that a large variety of oxides and mixed oxides show almost no increase in activity after treatment with much stronger HSO₃F. SiO₂–Al₂O₃ treated with Magic Acid was, however, found to be moderately active at room temperature in cracking butane, but its activity was much less than the Lewis acid-modified oxides (vide infra).

### 2.4.3.2. Lewis Acid-Modified Metal Oxides and Mixed Oxides.

In 1976, Tanabe and Hattori reported the preparation of solid superacids such as SbF₅–TiO₂–SiO₂, SbF₅–TiO₂, and SbF₅–SiO₂–Al₂O₃, whose acid strengths were in the range of −13.16 to −14.52 on the H₀ scale. In a subsequent work, the same authors reported a thorough study of the preparation and activity measurement of a large number of oxides and mixed oxides, treated with a variety of superacids. The SbF₅-treated oxides

such as TiO₂ and SiO₂, as well as mixed oxides like TiO₂–ZrO₂, TiO₂–SiO₂, SiO₂–Al₂O₃, were found to be most effective in the isomerization and cracking reactions of butane¹⁷⁰ and pentanes.¹⁷¹ The catalysts were prepared by exposing the powdered metal oxides to SbF₅ vapor at room temperature followed by degassing. The adsorption–desorption cycle was repeated a number of times, and finally the catalyst was subjected to high vacuum to remove last traces of free SbF₅ at a given temperature. The amount of SbF₅ remaining on the catalyst was measured by the weight increase of the catalyst.

The highest activity for butane cracking at room temperature was obtained with the TiO₂- and SiO₂-containing systems. For pentane and 2-methylpentane isomerizations at 0°C, the most active catalyst was SbF₅–TiO₂–ZrO₂ with a selectivity close to 100% for skeletal isomerization.

The high activity of these mixed oxides was ascribed to oxygen coordination of SbF₅ enhancing the acidity of both Brønsted and Lewis acid sites (Figure 2.21).

The activity and stability of aluminum chloride-treated alumina and silica–alumina as alkane isomerization catalysts has been investigated by Oelderik and Platteeuw.¹⁷² The degree of hydration of the carrier and the effects of hydrogen chloride and hydrogen pressure on the carrier have been studied. The authors concluded¹⁷² that AlCl₃ reacts with the hydrated carrier to give a surface-bound compound that is converted to an acidic site by HCl absorption. However, prolonged treatment of the carrier with excess AlCl₃ results in HCl gas evolution, until no acidic site is left on the catalyst. The activity of the catalyst system for hexane isomerization, however, declines exponentially with time.

Chlorinated alumina is still one of the most useful industrial catalyst for light alkane isomerization with generally a small amount of platinum being added in order to prevent coking.¹⁷³–¹⁷⁷

### 2.4.3.3. Lewis Acid-Complexed Metal Salts

Mixtures of aluminum chloride and metal chloride are known to be active for the isomerization of paraffins at room temperature.¹⁷⁸ Ono and co-workers¹⁷⁹–¹⁸³ have shown that the mixtures of aluminum halides with metal sulfates are much more selective for similar reactions at room temperature.

**AlCl₃–Metal Sulfates.** Room temperature isomerization of pentane has been carried out with a series of mixtures containing aluminum chloride with sulfates of metals such
as Ti, Fe(III), Ni, Cu, Mn, Fe(II), Al, Zr, Co, Mg, Ca, Ba, Pd, with conversions in excess of 10% after 3 h. The most effective catalyst was an equimolar mixture of AlCl₃ and Ti₂(SO₄)₃ with a conversion of 46% and a selectivity to isopentane of 84%. The catalysts were prepared by kneading a mixture of aluminum chloride and a dehydrated metal salt in a porcelain mortar in a dry nitrogen atmosphere. Even better catalyst performance was found for AlBr₃–Ti₂(SO₄)₃ (87% conversion, > 99% selectivity).

The AlCl₃–CuSO₄ mixture has been more thoroughly investigated in the 5–23°C temperature range. The acidity was estimated to be approximately $H_0 = -14$ and the activity was found to be proportional to the amount of CuSO₄ and also to the specific surface area of the CuSO₄ used. It was claimed that the addition of water had no effect on the catalytic activity, which seems to indicate that the active species are essentially different from those in the AlCl₃–H₂O system.

**AlCl₃–Metal Chlorides.** The catalytic activity of metal chloride–aluminum chloride mixtures for pentane isomerization has been studied by Ono. The highest conversion (31% after 3 h at room temperature) was found when AlCl₃ was combined with TiCl₃ (the latter was prepared by reducing TiCl₄ with Al and supposed to have a composition of TiCl₃–1/3AlCl₃), MnCl₂ (12%), and CuCl₂ (11%), but no such catalyst reached the activity of metal sulfate–aluminum halide mixtures.

### 2.4.4. Immobilized Superacids (Bound to Inert Supports)

Ways have been found to immobilize and/or to bind superacidic catalysts to an otherwise inert solid support. Several types are described in this section.

#### 2.4.4.1. Superacids Immobilized on Solid Supports

The considerable success of Magic Acid and related superacids in solution chemistry and interest to extend the scope and utility of acid-catalyzed reactions, particularly hydrocarbon transformations, logically led to the attempts to adopt this chemistry to solid systems allowing heterogeneous catalytic processes.

The acidity of perfluorinated sulfonic acids can be increased further by complexation with Lewis acid fluorides, such as SbF₅, TaF₅, and NbF₅. They have been found to be effective catalysts for $n$-hexane, $n$-heptane isomerization, alkylation of benzene, and transalkylation of alkylbenzenes (see Chapter 5).

Attempts have recently been made to prepare solid acids by loading triflic acid into various inert oxides including silica, titania, and zirconia. Silica functionalized with anchored aminopropyl groups was also used to immobilize triflic acid. These new catalysts have been tested in a variety of organic transformations, such as alkane–alkene alkylation, Friedel–Crafts acylation, alkene dimerization, and acetalization. Silica nanoboxes prepared by dealumination of Na–X- and Ca–A-type zeolites were also loaded with triflic acid up to 32 wt%. The materials were thoroughly characterized but have not been tested as catalysts.
Harmer et al.\textsuperscript{29} have applied the sol–gel technique to prepare 1,1,2,2-tetrafluoroethanesulfonic acid supported on silica, which proved to be an excellent catalyst for several processes such as alkylation and acylation of aromatics, isomerization, oligomerization, and Fries rearrangement. This material has activity similar to that of triflic acid but is much easier to handle.

Immobilization of fluoroboric acid (HBF\textsubscript{4}) on silica was also successfully performed,\textsuperscript{191,192} and the resulting material has shown good characteristics in catalytic transformations.

2.4.4.2. Graphite-Intercalated Superacids. The 1970s witnessed a renewal of interest and a virtual explosion in research in the preparation, structure, and properties of graphite intercalation compounds. A number of reviews\textsuperscript{193,194} have been devoted to this subject, showing that intercalation compounds can be useful materials as catalysts, reagents, electronic conductors, battery components, and lubricating agents. This research activity has continued ever since.\textsuperscript{195–198}

Graphite possesses a layered structure that is highly anisotropic. It consists of sheets of $sp^2$ carbon atoms in hexagonal arrays with a C–C bond distance of 1.42 Å consistent with a one-third double bond and two-thirds single bond character (Figure 2.22). The distance between the layers is 3.35 Å and is in accord with the fact that the graphite sheets are held together only by weak van der Waals forces. The atomic layers are not directly superimposable but alternate in the pattern A–B–A–B– as shown in Figure 2.22 for the most stable form, called hexagonal graphite. Two special types of synthetic graphite are considered of great interest: highly oriented pyrolytic graphite (HOPG) and graphite fibers. HOPG is a highly crystalline material in which all the carbon layers are nearly parallel in the whole sample, which may be of sizeable dimension. The graphite fibers are another form of synthetic graphite that show unusual mechanical properties in the composite material (used extensively in aviation industry).

The intercalation process has been a much disputed topic, but there is now sufficient experimental proof that the intercalation step is generally a redox process in which ions

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{Figure_2.22.png}
\caption{Graphite structure.}
\end{figure}
and neutral species enter the interlamellar space without disrupting the layered topology of graphite. X-ray studies show that the compounds at equilibrium favor the existence of a sequence of filled and empty interlamellar voids. This forms the basis for the concept of staging. In the first-stage (stage 1) compound, all the interlamellar regions are filled by the intercalant molecules (Figure 2.23). In the second- and third-stage compounds, each second or third interlamellar region, respectively, is filled by the intercalant and so on (Figure 2.23).

**AsF₅ and SbF₅ Graphite Intercalates.** Graphite reacts with AsF₅ (at 3 atm, 25°C) and SbF₅ to form the first-stage compounds C₈–AsF₅ and C₆.₅–SbF₅, respectively. At higher temperatures, higher-stage compounds can be prepared. For the AsF₅ compound, a composition shown in Eq. (2.33) has been proposed.¹⁹⁹

\[
8 \text{C} + \text{AsF}_5 \rightarrow \left(\text{C}_6^{0.33^+}\right)_{0.33}\left(\text{AsF}_6^-\right)_{0.33}\left(\text{AsF}_5\right)_{0.5}\left(\text{AsF}_3\right)_{0.17} \quad (2.33)
\]

During the insertion process, the metal is partially reduced from M(V) to the M(III) oxidation state and at the same time the neutral species are inserted. The same assumptions hold good for the SbF₅ inserted graphite for which ¹⁹F NMR,¹²¹¹² Sb Mossbauer,¹²²¹²³ and X-ray studies¹²⁴ have been conducted. Similar to the reactions of SbF₅ in liquid phase, an additional equilibrium is believed to take place in SbF₅–graphite intercalates [Eq. (2.34)], which is of significance in catalytic applications.

\[
\text{C}_n^{+}\text{MF}_6^- + \text{MF}_5 \rightarrow \text{C}_n^{+}\left(\text{M}_2\text{F}_{11}\right)^- \quad (2.34)
\]

The catalytic properties of SbF₅–graphite have been investigated.²⁰⁵–²⁰⁸ The chemistry is basically the same as that of SbF₅ itself with two major differences: (i) As a solid, it can be more easily separated from the reaction mixture, and (ii) the
activity is that expected from a very dilute solution of the superacid. The activity decreases, however, quite rapidly and the catalyst becomes deactivated after 10–20 turnovers. Three possible reasons for such a deactivation have been given by Heinerman and Gaaf: (i) leaching out of SbF₅, (ii) reduction of Sb(V) to Sb(III), and (iii) poisoning of the acidic sites by carbonaceous products.

Consequently, it is considered that the chemistry is not due to the graphite intercalate itself but to the SbF₅ present at the exposed surface areas. The reaction takes place at these reactive sites in the first step of the formation of the intermediate carbenium ion and SbF₅ is reduced to SbF₃. The carbenium ion itself may alkylate or undergo cleavage; and higher-molecular-weight polymeric material with increasing C:H ratio builds up on the catalytic site, thereby deactivating the catalyst slowly. X-ray diffraction studies and elemental analysis show that large quantities of SbF₅ exist in the deactivated catalyst and that the catalyst is not easily exfoliated (the lamellar structure is conserved and large regions of the first-stage compound can still be detected).

**Miscellaneous Superacid Intercalates.** The intercalation of AlCl₃ and AlBr₃ in graphite in the presence of chlorine or bromine has been long known. However, it was shown that the Lewis acids are readily leached out from the intercalates during Friedel–Crafts-type reactions, and it is not clear whether the intercalates themselves or more probably the surface-exposed Lewis acids are the de facto catalysts. Other superacids such as NbF₅, TaF₅, HF–SbF₅, and AlBr₃–Br₂ have also been used as graphite intercalates for various superacid-catalyzed reactions such as reduction of alkyl halides, alkylation of aromatics, and isomerization and cracking of C₅, C₆ alkanes.

**2.4.4.3. SbF₅-Fluorinated Graphite, SbF₅-Fluorinated Al₂O₃.** It has been shown that improved catalytic activity and stability is obtained with SbF₅-treated fluorinated graphites instead of graphite. Fluorinated graphites are not uniform in structure and contain many imperfections and nonfluorinated areas. It has also been demonstrated that SbF₅ is not intercalated into higher fluorinated graphite with a F:C ratio of 1.1; similar catalytic activity can be obtained by reacting SbF₅ with fluorinated γ-alumina. In less fluorinated samples it seems that SbF₅ is intercalated only in the nonfluorinated regions. The catalytic activity, however, is due to SbF₅ bound to the surface-exposed areas. The isomerization of pentane and hexane has been studied as a model reaction to assess the potential of SbF₅–graphite and SbF₅–fluorographite. A kinetic measurement of the deactivation process showed that nonfluorinated graphite–SbF₅ deactivated much more rapidly than fluorographite–SbF₅. It was suggested that in SbF₅–fluorographite, because of strong interaction with the carbon-bound fluorine and SbF₅, the catalyst is strongly immobilized. Better catalytic activity could be obtained by using fluorographite containing some graphite (with optimum at CF₀.₈), and it has been assumed that the initially intercalated SbF₅ leaches out of the layer during the isomerization and binds to the surface of fluorinated graphite, thereby creating a
new active site. The stability of the catalyst has been found comparable to SbF$_5$ bound to fluorinated $\gamma$-alumina. The characteristics of the hydroisomerization of pentane over SbF$_5$ on fluorinated graphite or fluorinated alumina, such as disproportionation reactions, influence of hydrogen pressure, stability, and deactivation mechanism are similar to those found with the homogeneous HF–SbF$_5$ liquid acid system.$^{209}$

CHAPTER 3

Carbocations in Superacid Systems

This chapter begins with a short historic retrospect about the development of the carbocation concepts and covers the techniques used for their generation, observation, and characterization under superacidic long-lived conditions. This is followed by an extensive coverage of the multitude of trivalent (classical) and equilibrating (degenerate) and higher (five or six) coordinate (nonclassical) carbocations.

Since the inception of the superelectrophilic concept in the 1970s\(^1\) and 1980s\(^2\) first formulated as protosolvation of cationic intermediates, superelectrophiles as highly reactive dicationic and tricationic intermediates have been successfully observed and characterized.\(^3\)–\(^5\) Consequently, selected examples of superelectrophiles are also covered in this chapter where appropriate, whereas various organic transformations, in which the involvement of superelectrophilic intermediates is invoked or superelectrophiles are observed, are treated in Chapter 5.

3.1. INTRODUCTION

3.1.1. Development of the Carbocation Concept: Early Kinetic and Stereochemical Studies

In the early 1900s, the pioneering work of Norris, Kehrmann, Baeyer, and others on triarylcarbenium salts generated wide interest in such species.\(^6\)–\(^9\) They were, however, long considered only of interest to explain the color of these dyes. One of the most daring and fruitful ideas born in organic chemistry was the suggestion that in the course of reactions, carbocations might be intermediates that start from nonionic reactants and lead to nonionic covalent products. It was H. Meerwein\(^10\) who in 1922, while studying the kinetics of the rearrangement of camphene hydrochloride to isobornyl chloride, reported the important observation that the reaction rate increased in a general way with the dielectric constant of the solvent. Furthermore, he found that metallic chlorides such as SbCl\(_5\), SnCl\(_4\), FeCl\(_3\), AlCl\(_3\), and SbCl\(_3\) (but not BCl\(_3\) or SiCl\(_4\)), as well as dry HCl, which promote ionization of triphenylmethyl chloride by
the formation of ionized complexes, considerably accelerated the rearrangement of camphene hydrochloride. Meerwein concluded that the conversion of camphene hydrochloride to isobornyl chloride actually does not proceed by way of migration of the chlorine atom but by a rearrangement of a cationic intermediate. Thus, the modern concept of carbocation intermediates was born.

Ingold, Hughes, and their collaborators in England, beginning in the late 1920s, carried out detailed kinetic investigations on what later became known as nucleophilic substitution at saturated carbon and polar elimination reactions. The well-known work relating to $S_{N}1$ and later $E1$ reactions established the carbocation concept in these reactions. Whitmore, in a series of papers that began in 1932, generalized Meerwein’s rearrangement theory to many organic chemical reactions, although he cautiously avoided writing positive signs on any of the intermediates.

Kinetic and stereochemical evidence helped to establish carbocation intermediates in organic reactions. These species, however, were generally too short-lived and could not be directly observed by physical means.

3.1.2. Observation of Stable, Long-Lived Carbocations

The transient nature of carbocations arises from their extreme reactivity with nucleophiles. The use of low-nucleophilicity counterions, particularly tetrafluoroborates ($\text{BF}_4^-$), enabled Meerwein in the 1940s to prepare a series of oxonium and carboxonium ion salts, such as $\text{R}_3\text{O}^+\text{BF}_4^-$ and $\text{HC(OR)}_2^+\text{BF}_4^-$, respectively. These Meerwein salts are effective alkylating agents, and they transfer alkyl cations in $S_{N}2$-type reactions. However, simple alkyl cation salts ($\text{R}^+\text{BF}_4^-$) were not obtained in Meerwein’s studies. The first acetyl tetrafluoroborate—that is, acetylium tetrafluoroborate—was obtained by Seel in 1943 by reacting acetyl fluoride with boron trifluoride at low temperature [Eq. (3.1)].

$$\text{CH}_3\text{COF} + \text{BF}_3 \rightarrow \text{CH}_3\text{CO}^+\text{BF}_4^- \quad (3.1)$$

In the early 1950s, Olah and co-workers started a study of the intermediates of Friedel–Crafts reactions and inter alia carried out a systematic investigation of acyl fluoride–boron trifluoride complexes. They were able to observe a series of donor–acceptor complexes as well as stable acyl cations. Subsequently, the investigations were also extended to other Lewis acid halides. In the course of these studies, they increasingly became interested in alkyl halide–Lewis acid halide complexes. The study of alkyl fluoride–boron trifluoride complexes by electrical conductivity measurements indicated the formation of ionic complexes in the case of tert-butyl and isopropyl fluoride at low temperatures, whereas methyl and ethyl fluoride formed molecular coordination complexes. Subsequently, Olah and co-workers initiated a systematic study of more suitable acid and low-nucleophilicity solvent systems. This resulted in the discovery of (a) antimony pentafluoride as a suitable very strong Lewis acid, (b) related superacid systems such as Magic Acid.
(HSO₃F–SbF₅), and (c) low-nucleophilicity solvent systems such as SO₂, SO₂ClF, and SO₂F₂, which finally allowed obtaining alkyl cations as stable, long-lived species. Subsequently, by the use of a variety of superacids, a wide range of practically all conceivable carbocations became readily available for structural and chemical studies.

3.1.3. General Concept of Carbocations

Electrophilic reactions since Meerwein’s pioneering studies are generally considered to proceed through cationic (i.e., carbocationic) intermediates. The general concept of carbocations encompasses all cations of carbon-containing compounds, which sometimes were differentiated into two limiting classes: (i) trivalent (“classical”) carbenium ions and (ii) five or higher coordinate (“nonclassical”) carbonium ions. Whereas the differentiation of limiting trivalent carbenium and pentacoordinate carbonium ions serves a useful purpose to establish the significant differences between these ions, it is also clear that in most specific systems there exists a continuum of charge delocalization. In fact, in all carbocations (even in the parent CH₃⁺), there is a continuum of degree of charge delocalization, and thus to think in limiting terms is rather meaningless. Participation by neighboring groups can be not only by n- and π-donors, as most generally recognized, but also by σ-ligands. There is in principle no difference between these electron donors. σ-Participation in properly oriented systems is not only possible, but is unavoidable. The only question is its degree and not whether it exists.

It is well known that trivalent carbenium ions play an important role in electrophilic reactions of π- and n-donors systems. Similarly, pentacoordinate carbonium ions are the key to electrophilic reactions of σ-donor systems (single bonds). The ability of single bonds to act as σ-donors lies in their ability to form carbonium ions via delocalized two-electron, three-center (2e–3c) bond formation. Consequently, there seems to be in principle no difference between the electrophilic reactions of π- and σ-bonds except that the former react more easily even with weak electrophiles, whereas the latter necessitate more severe conditions.

On the basis of the study of carbocations by direct observation of long-lived species, it became increasingly apparent that the carbocation concept is much wider than previously realized and necessitated a general definition. Therefore, such a definition was offered based on the realization that two distinct, limiting classes of carbocations exist (Figure 3.1).

1. Trivalent (“classical”) carbenium ions contain an sp²-hybridized electron-deficient carbon center that tends to be planar in the absence of constraining skeletal rigidity or steric interference. (It should be noted that sp-hybridized, linear acyl cations and vinyl cations also show substantial electron deficiency on carbon.) The carbenium carbon contains six valence electrons, and thus it is highly electron-deficient. The structure of trivalent carbocations can always be adequately described by using two-electron, two-center bonds (Lewis valence bond structures).
2. Penta(or higher)-coordinate ("nonclassical") carbonium ions, which contain five (or higher) coordinate carbon atoms, cannot be described by two-electron single bonds alone, but also necessitates the use of two-electron, three-center (or multicenter) bond(s). The carbocation center is always surrounded by eight electrons, although two (or more) of them are involved in multicenter bonds, and thus such ions are overall electron-deficient (due to electron-sharing of two binding electrons between three (or more) centers).

Lewis’s concept that a chemical bond consists of a pair of electrons shared between two atoms became the foundation of structural chemistry, and chemists still tend to name compounds as anomalous when their structures cannot be depicted in terms of such bonds alone. Carbocations with too few electrons to allow a pair for each “bond” came to be referred to as “nonclassical,” a label still used even though it is now recognized that, like many other substances, they adopt the delocalized structures appropriate for the number of electrons they contain.

Expansion of the carbon octet via $3d$-orbital participation does not seem possible; there can be only eight valence electrons in the outer shell of carbon.$^{22,23}$ Thus, the covalency of carbon cannot exceed four. Penta(or higher)-coordination implies a species with five (or more) ligands within reasonable bonding distance from the central atom.$^{24}$ The transition states long ago suggested for $S_{N}2$ reactions represent such cases, but involving 10 electrons around the carbon center. Charge–charge repulsions in the $S_{N}2$ transition state forces the entering and leaving substituents as far apart as possible leading a trigonal bipyramid with a long $4e–3c$ bond allowing little possibility of a stable intermediate. In contrast, $S_{E}2$ substitution reactions involve $2e–3c$ interactions but have been in the past mainly restricted to organometallic compounds (e.g., organomercurials)$^{25}$.

The direct observation of stable penta(or higher)-coordinate species with eight electrons around the carbon center in solutions was not reported until recent studies of long-lived “nonclassical” ions in superacid solvent systems.

Neighboring group interactions with the vacant $p$ orbital of the carbenium ion center can contribute to ion stabilization via charge delocalization. Such phenomena can involve atoms with unshared electron pairs ($n$-donors), $C=H$ and $C=C$ hyper-conjugation, bent $\sigma$-bonds (as in cyclopropylcarbenium ions), and $\pi$-electron systems (direct conjugative or allylic stabilization). Thus, trivalent carbenium ions can show

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{Figure3.1.png}
\caption{Classification of carbocations.}
\end{figure}
varying degrees of delocalization without becoming pentacoordinate carbonium ions. The limiting classes defined do not exclude varying degrees of delocalization, but in fact imply a spectrum of carbocation structures.

In contrast to the rather well-defined trivalent (“classical”) carbenium ions, “nonclassical ions” have been more loosely defined. In recent years, a lively controversy centered on the classical–nonclassical ion problem. The extensive use of “dotted lines” in writing carbonium ion structures has been (rightly) criticized by Brown, who carried, however, the criticism to question the existence of any \( \sigma \)-delocalized (nonclassical) ion. For these ions, if they exist, he stated “...a new bonding concept not yet established in carbon structures is required.”

Clear, unequivocal experimental evidence has by now been obtained for nonclassical ions such as the norbornyl cation. The bonding concept required to define “nonclassical ions” is simply to consider them as penta(or higher)-coordinated carbocation ions involving at least one two-electron three-center (or multicenter) bond, of which \( \text{CH}_5^+ \) (the methonium ion–carbonium ion) is the parent, as \( \text{CH}_3^+ \) (the methenium ion, methyl cation, carbenium ion) is the parent for trivalent carbenium ions. An example of a hexacoordinate carbonium ion is the pyramidal dication of Hogeveen.

Concerning the carbocation concept, it is regrettable that for a long time in the Anglo-Saxon literature the trivalent planar ions of the \( \text{CH}_3^+ \) type were named as carbonium ions. If the name considered analogous to the other -onium ions (ammonium, sulfonium, phosphonium ions, etc.), then it should relate to the higher-valency or coordination-state carbocations. The higher-bonding-state carbocations, however, clearly are not the trivalent but the penta(or higher)-coordinate cations. The German and French literatures indeed frequently used the “carbenium ion” naming for the trivalent cations. If one considers these latter ions as protonated carbenes, the naming is indeed correct. It should be pointed out, however, that the “carbenium ion” naming depicts only trivalent ions and thus should not be a general name for all carbocations. IUPAC’s Organic Chemistry Division has reviewed the nomenclature of physical organic chemistry and recommends the use of the “carbocation” for naming all positive ions of carbon. The namings “carbenium” or “carbonium ion,” similar to the “carbinol” naming of alcohols, is discouraged.

### 3.2. METHODS OF GENERATING CARBOCATIONS IN SUPERACIDS SYSTEMS

Common superacid systems that are generally employed in the preparation of carbocations are the Brønsted acids such as HSO\(_3\)F and HF and Lewis acids such as SbF\(_5\). Also, Lewis and Brønsted acid combinations such as HSO\(_3\)F–SbF\(_5\) (Magic Acid), HSO\(_3\)F–SnF\(_5\) (4:1), and HF–SnF\(_5\) (fluoroantimonic acid) have been used. Other superacid systems such as HF–BF\(_3\), AsF\(_5\), CF\(_3\)SO\(_2\)H, HF–PF\(_5\), HCl–AlCl\(_3\), HBr–AlBF\(_3\), H\(_2\)SO\(_4\), and HClO\(_4\) have been successfully adopted. Sometimes a metathetic reaction involving a halide precursor and AgBF\(_4\) or AgSbF\(_6\) has also been successful. The most convenient non-nucleophilic solvent systems used in the preparation of carbocations are SO\(_2\), SO\(_2\)ClF, and SO\(_3\)F\(_2\). To be able to study ionic
Carbocations are often unstable and cannot be isolated as pure samples. However, by performing experiments at very low temperatures (ca. $-160^\circ$C) by NMR spectroscopy, Freons like CHCl$_2$F may be used as a co-solvent to decrease the viscosity of the solution.

The success of a carbocation preparation is superacid generally depends on the technique employed. For most of the stable systems, Olah’s method$^{44}$ of mixing the precooled progenitor dissolved in appropriate solvent system along with the superacid using a simple vortex stirrer to mix the components is generally convenient. However, care should be taken to avoid moisture and local heating. Low temperatures between $-78^\circ$C (using acetone–dry ice) and $-120^\circ$C (using liquid N$_2$–ethanol slush), which suppress side reactions like dimerization and oligomerizations, are most commonly employed.

Methods for the generation of very reactive carbocations have been developed most notably by Ahlberg$^{45}$ and Saunders et al.$^{46}$ The former group describes an ion-generation apparatus that consists of a Schlenk tube-like vessel attached to an NMR tube in which the carbocation is prepared at low temperatures. This methodology has been further improved.$^{47,48}$

The method of Saunders,$^{46}$ however, is more sophisticated. It uses deposition of the starting reagents from the gas phase (using high vacuum) on a surface cooled to liquid nitrogen temperature to produce stable solutions of carbocations. The details of the method have been published in detail.$^{49}$ Myhre and Yannoni$^{50}$ have successfully utilized the above method to generate carbocations in an SbF$_5$ matrix at very low temperatures for their solid-state$^{13}$C NMR spectroscopic work.

Kelly and Brown$^{51}$ describe a method for the preparation of concentrated solutions of carbocations ($\sim 1 \text{ M}$) in SbF$_5$–SO$_2$ClF. This method, which employs a syringe technique, allows quantitative conversion of precursors soluble in SO$_2$ClF at $-78^\circ$C into the corresponding carbocations.

### 3.3. METHODS AND TECHNIQUES IN THE STUDY OF CARBOCATIONS

#### 3.3.1. Nuclear Magnetic Resonance Spectra in Solution

One of the most powerful tools in the study of carbocations is nuclear magnetic resonance (NMR) spectroscopy. This method yields direct information—through chemical shifts, coupling constants, and the temperature dependence of band shapes—about the structure and dynamics of carbocations.

Although the initial developments in the observation of stable carbocations in solution relied heavily upon $^1$H NMR spectroscopy, $^{13}$C NMR spectroscopy has proven to be the single most useful technique. $^{13}$C NMR permits the direct observation of the cationic center, and the chemical shifts and coupling constants can be correlated to the cation geometry and hybridization. At the beginning of the $^{13}$C NMR studies in the early 1960s, Olah and co-workers used the INDOR technique to obtain spectra of carbocations at natural $^{13}$C abundance. In the past decades, the development of the Fourier transform NMR spectrometers has made available $^1$H and $^{13}$C NMR spectra of very dilute solution of cations. The signal-to-noise (S/N) ratio has been further improved by the introduction of high-field superconducting magnets. With such
Degenerate rearrangement reaction rate constants of the order $10^7$ s$^{-1}$, which corresponds to a free energy of activation of $3.3$ kcal mol$^{-1}$ at $-160^\circ$C, have been measured.

Degenerate rearrangements of carbocations, if they are fast enough, result in temperature-dependent NMR spectra. At slow exchange, the signals of the exchanging nuclei show up as separate absorptions. If the exchange rate is gradually increased by raising the temperature, the signals first broaden and, upon a further rise in the temperature, coalesce. Still further increase of the exchange rate results in sharpening of the broad coalesced signals (Figure 3.2).

The formula in Figure 3.2c shows that the larger the shift difference ($\nu_{AB}$) between the exchanging signals, the larger the rate constant needed to get coalescence at a specific temperature. Thus, since chemical shift differences in $^{13}$C NMR are usually much larger (in Hz) than in $^1$H NMR, $^{13}$C NMR spectroscopy permits the quantitative study of much faster processes than can be investigated by $^1$H NMR spectroscopy.

Very slow exchange could be detected and the rate measured by the transfer of spin saturation, a tool that could be useful in the elucidation of reaction mechanisms causing exchange. One of the signals participating in very slow exchange is saturated by an extra RF field while the rest of the spectrum is observed. If exchange of the spin-saturated nuclei takes place at a rate comparable to that of the nuclear-spin relaxation ($T_1$), then transfer of the spin saturation by the degenerate reaction will partially saturate the other exchanging nuclei. From the degree of transferred spin saturation and measured $T_1$, the rate of exchange could be evaluated. This technique was devised by Forsén and Hoffman$^{52,53}$ using $^1$H NMR spectroscopy, and it has been utilized in the study of carbocations. The method has some limitations with $^1$H NMR due to the small shift differences and large couplings between the protons. However, the method has recently been applied using $^{13}$C NMR spectroscopy (proton decoupled) for study of complex carbocation rearrangements.$^{54}$

### 3.3.2. $^{13}$C NMR Chemical Shift Additivity

An empirical criterion based on additivity of $^{13}$C NMR chemical shifts for distinguishing classical trivalent and higher coordinate carbocations has been developed by
Schleyer, Olah, and co-workers. In this method, the sums of all $^{13}$C chemical shifts of carbocations with their respective hydrocarbon precursors are compared. A trivalent carbocation has a sum of chemical shifts of at least 350 ppm higher than the sum for the corresponding neutral hydrocarbon. This difference can be rationalized by partly attributing it to the hybridization change to $sp^2$ and to the deshielding influence of an unit positive charge in the trivalent carbocation. Since higher coordinate carbocations (nonclassical ions) have penta- and hexa-coordinate centers, the sum of their chemical shifts relative to their neutral hydrocarbons is much smaller, often by less than 200 ppm.

### 3.3.3. Isotopic Perturbation Technique

The deuterium isotopic perturbation technique developed by Saunders and co-workers is capable of providing a convenient means to differentiate the rapidly equilibrating or bridged nature of carbocations.

In 1971, Saunders and Vogel discovered that by asymmetrically introducing deuterium into some reversible rearrangement processes of carbocations, large splittings were produced in their NMR spectra. Although the ions were interconverting extremely rapidly and thus gave averaged spectra, the isotope made the energies of the two interconverting species slightly different and thus the equilibrium constant between them was no longer 1. Each ion, therefore, spent a little more time on one side of the equilibrium barrier than on the other side. The weighted-average peaks of the two carbon atoms that were interchanged by the rearrangement process no longer coincided. Splitting values in the $^{13}$C NMR spectrum of over 100 ppm were observed as a result of perturbation by deuterium.

However, when deuterium was introduced into systems that are recognized as static, single-minimum, nonequilibrating species, such as the cyclohexenyl cation, no large splittings were observed and, in contrast to the behavior of the equilibrating systems, there were no observable changes in the spectra with temperature. In fact, the isotope-induced changes in the spectra were not very different from changes that occur in any simple molecule on introducing deuterium, and they were roughly only 50 times smaller than effects produced in the equilibrating systems.

These observations led to the method of observing changes in NMR spectra produced by asymmetric introduction of isotopes (isotopic perturbation) as a means of distinguishing systems involving equilibrating species passing rapidly over a low-energy barrier from molecules with a single energy minimum, intermediate between the presumed equilibrating structures. Application of this method for individual carbocations will be discussed later. This method also allows accurate determination of equilibrium isotope effects.

### 3.3.4. Solid-State $^{13}$C NMR

The use of magic-angle spinning (MAS) and cross-polarization (CP) techniques has enabled high-resolution $^{13}$C NMR spectra to be obtained in the solid state. Yannoni, Myhre, and Fyfe have obtained solid-state NMR spectra of frozen carbocation
solutions (such as alkyl cations, the norbornyl cation, etc.) at very low temperatures\textsuperscript{50,63,64} (even at 5 K). At such low temperatures, rearrangements and most molecular motions can be frozen out. Olah’s group has studied a series of stable carbocations, including the 1-adamantyl cation, acyl cations, and so on, by $^{13}$C CPMAS at ambient temperature. In these studies solid-state effects seem to be unimportant on chemical shifts (as compared to solution data) but are significant on rates of exchange processes.\textsuperscript{63,64}

**3.3.5. X-ray Diffraction**

X-ray diffractometry is the most powerful method to determine atomic coordinates of molecules in the solid state. X-ray crystal structure analysis was, however, rarely applied in the early years of development of persistent, long-lived alkyl carbocations and studies were only performed to investigate structures of carbocations of aryl derivatives and aromatic systems.\textsuperscript{65} This is due to the low thermal stability of alkyl carbocations and to the difficulties in obtaining single crystals of carbocations suitable for analysis. Since then, however, methods and instrumentation have improved significantly and X-ray crystal structure analysis has become a powerful tool to solve structural problems of carbocations.\textsuperscript{65,66}

**3.3.6. Tool of Increasing Electron Demand**

The nature of electronic effects in cationic reactions has been probed by application of the Gassman–Fentiman tool of increasing electron demand.\textsuperscript{67} Aryl-substituted cationic centers can be made more electron demanding (i.e., electrophilic) by introduction of electron-withdrawing substituents into the aryl ring.

When a cationic center becomes sufficiently electrophilic, it may draw on electrons from neighboring $\pi$- and $\sigma$-bonds and thus delocalize positive charge density. The onset of participation of $\pi$- and $\sigma$-bonds can be detected as a departure from linearity in a Hammett-type plot as the electron-withdrawing ability of the aryl substituent increases. In stable ion studies, $^{13}$C NMR chemical shifts are generally used as a structural probe reflecting the charge density at the cation center (in closely related homologous cations, other factors that may affect chemical shift may be assumed constant).

The tool of increasing electron demand has proved useful in detecting the onset of $\pi$- and $\sigma$-delocalizations under stable-ion conditions. It is, however, an extremely coarse technique since the aryl group can still delocalize charge into its $\pi$-system, even with strongly electron-withdrawing substituents. Only in cases where neighboring $\sigma$- and $\pi$-bonds can effectively compete with the aryl ring in stabilizing the cationic center are significant deviations from linearity observed in the Hammett-type plot.

**3.3.7. Core Electron Spectroscopy**

X-ray photoelectron spectroscopy measures the energy distribution of the core electrons emitted from a compound on irradiation with X rays.\textsuperscript{68,69} The electron
binding energy \( (E_b) \) is a function of the chemical environment of the atom. In particular, the atomic charge on carbon can be directly correlated to the carbon 1s electron binding energy.\(^{70}\) The cationic center of a classical carbocation (e.g., tert-butyl cation) has a carbon 1s \( E_b \) approximately 4 eV \textit{higher} than a neutral \( sp^3 \) carbon atom.\(^{70}\) Electron deficiencies of different degrees in different carbocations give different carbon core electron 1s binding energies; the delocalization of charge from a cationic center lowers the carbon 1s binding energy.

Core electron spectroscopy for chemical analysis (ESCA) is perhaps the most definitive technique applied to the differentiation between nonclassical carbocations from equilibrating classical species. The time scale of the measured ionization process is of the order of \( 10^{-16} \) s so that definite species are characterized, regardless of (much slower) intra- and intermolecular exchange reactions—for example, hydride shifts, Wagner–Meerwein rearrangements, proton exchange, and so on.

**3.3.8. Infrared and Raman Spectroscopy**

Infrared and Raman spectra of stable carbocations have been obtained\(^{71,72}\) and are in complete agreement with their electron-deficient structures. Infrared spectra of alkyl cations and their deuteriated analogs correspond to the spectra predicted by calculations based on molecular models and force constants. Thus, these spectra can be used in the identification of stable carbocations.

Laser Raman spectroscopy, particularly with helium–neon lasers, is another powerful tool in the study of carbocations. Because Raman spectra give valuable information on symmetry, these spectra help to establish, in detail, structures of the ions and their configurations.

**3.3.9. Electronic Spectroscopy**

The observation of stable alkyl cations in antimony pentafluoride solutions also opened up the possibility of investigating the electronic spectra of these solutions. It has been reported\(^{73}\) that solutions of alkyl cations in \( \text{HSO}_3\text{F–SbF}_5 \) solution at \(-60^\circ\text{C}\) showed no absorption maxima above 210 nm. In view of this observation, it was resolved that previous claims relating to a 290-nm absorption of alcohols and alkenes in sulfuric acid solutions were due to condensation products or cyclic allylic ions and not to simple alkyl cations.\(^{74}\)

**3.3.10. Low-Temperature Solution Calorimetric Studies**

Arnett and co-workers,\(^{75,76}\) in a series of investigations, have determined heats of ionization \( (\Delta H_i) \) of secondary and tertiary chlorides and alcohols in \( \text{SbF}_5–\text{SO}_2\text{ClF} \) and \( \text{HSO}_3\text{F–SbF}_5–\text{SO}_2\text{ClF} \) solutions, respectively, at low temperatures. They have also measured heats of isomerizations of secondary to tertiary carbocations in the superacid media. These measured thermochemical data have been useful to determine the intrinsic thermodynamic stability of secondary and tertiary carbocations.
3.3.11. Quantum Mechanical Calculations

One of the main aims of quantum mechanical methods in chemistry is the calculation of energies of molecules as a function of their geometries. This requires the generation of potential energy hypersurfaces. If these surfaces can be calculated with sufficient accuracy, they may be employed to predict equilibrium geometries of molecules, relative energies of isomers, the rates of their interconversions, NMR chemical shifts, vibrational spectra, and other properties. Carbocations are ideally suited for calculations because relative energies of well-defined structural isomers are frequently not easily determined experimentally. It should, however, be kept in mind that theoretical calculations usually refer to isolated ion structures in the gas phase.

Over the years, several computational methods have been developed. The variational theory can be used either without using experimental data other than the fundamental constants (i.e., ab initio methods) or by using empirical data to reduce the needed amount of numerical work (i.e., semiempirical data methods). There are various levels of sophistication in both ab initio [HF(IGLO), DFT GIAO-MP2, GIAO-CCSD(T)] and semiempirical methods. In the ab initio methods, various kinds of basic sets can be employed, while in the semiempirical methods, different choices of empirical parameters and parametric functions exist. The reader is referred to reviews of the subject.18,77

Recent developments in computational chemistry have established the exact structure of carbocations by combining computational and experimental results.78,79 Furthermore, accurate 1H and 13C NMR chemical shifts of carbocations and other organic molecules can be calculated with the application of recent coupled cluster methods, such as GIAO-CCSD(T).80

3.4. TRIVALENT CARBOCATIONS

3.4.1. Alkyl Cations

3.4.1.1. Early Unsuccessful Attempts. Until the early 1960s, simple alkyl cations were considered only as transient species.15 Their existence has been inferred from the kinetic and stereochemical studies of reactions. No reliable physical measurements, other than electron impact measurements in the gas phase (mass spectrometry), were known. The formation of gaseous organic cations under electron bombardment of alkenes, haloalkanes, and other precursors has been widely investigated in mass spectrometric studies.81 No direct observation of carbocations in solutions was achieved prior to the early 1960s.

The observation of alkyl cations such as the tert-butyl cation [trimethylcarbenium ion, (CH₃)₃C⁺] 1 and the isopropyl cation [dimethylcarbenium ion, (CH₃)₂CH⁺] 2 was a long-standing challenge. The existence of alkyl cations in systems containing alkyl halides and Lewis acids has been inferred from a variety of observations, such as vapor pressure depressions of CH₃Cl and C₂H₅Cl in the
presence of GaCl$_3$, conductivity of AlCl$_3$ in alkyl chlorides, and conductivity of alkyl fluorides in BF$_3$, as well as the effect of ethyl bromide on the dipole moment of AlBr$_3$. However, in no case had well-defined, stable cation complexes been established even at very low temperatures.

Electronic spectra of alcohols and alkenes in strong proton acids (H$_2$SO$_4$) were obtained by Rosenbaum and Symons. They observed, for a number of simple aliphatic alcohols and alkenes, absorption maxima around 290 nm and ascribed this absorption to the corresponding alkyl cations.

Finch and Symons, on reinvestigation of the absorption of aliphatic alcohols and alkenes in sulfuric acid solution, showed that the condensation products formed with acetic acid (used as solvent for the precursor alcohols and alkenes) were responsible for the spectra and not the simple alkyl cations. Moreover, protonated mesityl oxide was identified as the absorbing species in the system of isobutylene, acetic acid, and sulfuric acid.

Deno has carried out an extensive study of the fate of alkyl cations in undiluted H$_2$SO$_4$ and oleum. He obtained equal amounts of a saturated hydrocarbon mixture (C$_4$–C$_{19}$) insoluble in H$_2$SO$_4$ and a mixture of cyclopentenyl cations (C$_9$–C$_{10}$) in the H$_2$SO$_4$ layer. These cations exhibit strong UV absorption around 300 nm.

Therefore, it must be concluded that earlier attempts to prove the existence of stable, well-defined alkyl cations were unsuccessful in experiments using sulfuric acid solutions and inconclusive in the interaction of alkyl halides with Lewis acid halides. Proton elimination reactions or dialkyl halonium ion formation may have affected the early conductivity studies.

### 3.4.1.2. Preparation from Alkyl Fluorides in Antimony Pentafluoride Solution and Spectroscopic Studies

In 1962, Olah et al. first directly observed alkyl cations in solution. They obtained the tert-butyl cation (trimethylcarbenium ion) when tert-butyl fluoride was dissolved in excess antimony pentafluoride, which serves as both Lewis acid and solvent. Later, the counterion was found to be, under these conditions, primarily the dimeric Sb$_2$F$_{11}^-$ anion [Eq. (3.2)] whereas in SbF$_5$–SO$_2$ or SbF$_5$–SO$_2$ClF solutions, SbF$_5^-$ and Sb$_2$F$_{11}^-$ are both formed.

$$\text{(CH}_3\text{)}_3\text{CF} + \text{(SbF}_3\text{)}_2 \rightarrow \text{(CH}_3\text{)}_3\text{C}^+\text{Sb}_2\text{F}_{11}^- \quad (3.2)$$

The possibility of obtaining stable alkyl pentafluoroantimonate salts from alkyl fluorides (and subsequently other alkyl halides) in antimony pentafluoride solution (neat or diluted with sulfur dioxide, sulfonyl chloride fluoride, or sulfonyl fluoride) or in other superacids (for a definition, see Chapter 1) such as HSO$_3$F–SbF$_5$ (Magic Acid), HF–SbF$_5$ (fluoroantimonic acid), HF–TaF$_5$ (fluorotantalic acid), and the like, was evaluated in detail, extending studies to all isomeric C$_3$–C$_8$ alkyl halides, as well to a number of higher homologs.

Propyl, butyl, and pentyl fluorides with antimony pentafluoride gave the isopropyl, tert-butyl, and tert-pentyl cations (as their fluoroantimonate salts) 2, 1, and 3,
respectively [Eqs. (3.3)–(3.5)].

$$C_3H_7F + (SbF_5)_2 \rightarrow CH_3-\overset{+}{C}CH-CH_3 SbF_{11}^- \quad (3.3)$$

$$C_4H_9F + (SbF_5)_2 \rightarrow CH_3-\overset{+}{C}CH-CH_3 SbF_{11}^-  \quad (3.4)$$

$$C_5H_{11}F + (SbF_5)_2 \rightarrow CH_3-\overset{+}{C}CH_2CH_3 SbF_{11}^- \quad (3.5)$$

The secondary butyl and amyl cations can be observed only at very low temperatures, and they rearrange readily to the more stable tertiary ions. Generally, the most stable tertiary or secondary carbocations are observed from any of the isomeric alkyl fluorides in superacidic solvent systems.

The main feature of the proton NMR spectra of alkyl fluorides in antimony pentafluoride is the substantial deshielding of the protons in the carbocations as compared with the starting alkyl fluorides (Figure 3.3 and Table 3.1).

---

**Figure 3.3.** $^1$H NMR spectra of (a) the tert-butyl cation 1 [trimethylcarbenium ion, $(CH_3)_3C^+$], (b) the tert-pentyl cation 3 [ethyldimethylcarbenium ion, $C_2H_5(CH_3)_2C^+$], and (c) the isopropyl cation 2 [dimethylcarbenium ion, $(CH_3)_2HC^+$] (60 MHz, SbF$_5$–SO$_2$ClF solution, $-60^\circ$C).
To prove that stable alkyl cations, and not exchanging donor–acceptor complexes, were obtained, Olah and co-workers also investigated as early as 1962 the $^{13}$C NMR of the potentially electropositive carbenium carbon atom in alkyl cations.\textsuperscript{94} The $^{13}$C\textsuperscript{+} shift in the tert-butyl cation (CH$_3$)$_3$C\textsuperscript{+} in SbF$_5$–SO$_2$ClF solution at $-20^\circ$C is at $\delta^{13}$C 335.2 (all $^{13}$C NMR shifts are from $^{13}$C tetramethylsilane) with a long-range coupling to the methyl protons of 3.6 Hz.

The $^{13}$C\textsuperscript{+} shift of the isopropyl cation\textsuperscript{2} under identical conditions, is $\delta^{13}$C 320.6 with a long-range coupling to the methyl protons of 3.3 Hz. The direct $^{13}$C–H coupling is 169 Hz (indicating $sp^2$ hybridization of the carbenium carbon atom), whereas the long-range proton–proton coupling constant is 6.0 Hz (see Figure 3.2). Substitution of the methyl group in the tert-butyl cation by hydrogen causes an upfield shift of 10.4 ppm. Although the $^{13}$C NMR shift of the carboxation center of the tert-butyl cation is more deshielded than that of the isopropyl cation (by about 10 ppm), this can be explained by the methyl substituent effect, which may sometimes amount up to 22 ppm. The tert-butyl cation thus is more delocalized and stable than the secondary isopropyl cation.

The $^{13}$C\textsuperscript{+} shift in the tert-pentyl cation [C$_2$H$_5$(CH$_3$)$_2$C\textsuperscript{+}]\textsuperscript{3} is at $\delta^{13}$C 335.4, which is similar to the that of the tert-butyl cation. The shift difference is much smaller than the 17 ppm found in the case of the related alkanes, although the shift observed is in the same direction. The $^{13}$C NMR chemical shifts and coupling constants $J_{C-H}$ of C$_3$ to C$_8$ alkyl cations 1–13 are shown in Tables 3.2 and 3.3.\textsuperscript{95}

It is difficult to interpret these large deshieldings in any way other than as a direct proof that (i) the hybridization state of the carbon atom at the carbenium ion center is $sp^2$ and (ii) at the same time, the $sp^2$ center carries a substantial positive charge.

Data in Tables 3.2 and 3.3 are characterized by substantial chemical shift deshieldings and coupling constants ($J_{C-H}$) that indicate $sp^2$ hybridization. Also subsequently, Myhre and Yannoni\textsuperscript{50} have obtained $^{13}$C NMR spectrum of tert-butyl cation 1 in the solid state, which agrees very well with the solution data.\textsuperscript{95}

The temperature-dependent $^1$H NMR spectrum of isopropyl cation\textsuperscript{2} (prepared from isopropyl chloride in SbF$_5$–SO$_2$ClF solution) demonstrated\textsuperscript{96} rapid interchange of two types of protons. Line-shape analysis showed the reaction to be intramolecular, with an activation energy barrier of 16.4 ± 0.4 kcal mol$^{-1}$. Based on these observations, Saunders and Hagen\textsuperscript{96} suggested that the rearrangement involves $n$-propyl...

All values are measured in hertz.
cation 14 as an intermediate [Eq. (3.6)] and that the activation energy provides an estimate of the energy difference between primary and secondary carbocations. Another mechanism involving protonated cyclopropane intermediates could not be excluded with the above results.

\[
\text{(I)} \quad \begin{array}{c}
\text{CH}_3 - \cdot \text{H} - \text{CH}_3 \\
\text{2} \\
\text{CH}_3 - \cdot \text{H} - \text{CH}_2 \\
\text{14} \\
\text{CH}_3 - \cdot \text{H} - \text{CH}_3 \\
\text{2}
\end{array} \quad (3.6)
\]

Strong support for the involvement of protonated cyclopropane intermediates came from the work of Olah and White.\textsuperscript{94} The isopropyl cation obtained from [2-\textsuperscript{13}C]2-chloropropane (50% \textsuperscript{13}C) was studied by \textsuperscript{1}H NMR. The \textsuperscript{13}C label scrambled uniformly over 1 and 2 positions at \(-60^\circ\text{C}\) within a few hours (half life \(\approx 1\text{ h}\)).

The relative rates of hydrogen and carbon interchange have been measured by Saunders et al.\textsuperscript{97} using a mixture of [1,1,1-\textsuperscript{2}H\textsubscript{3}] and [2-\textsuperscript{13}C]-labeled isopropyl cations at \(-88^\circ\text{C}\). The changes in the relative areas of different peaks as well as \textsuperscript{13}C satellites were observed, and the time dependence of the concentrations of different labeled isomers were simulated using a computer [using mechanisms (I), (II), and (III) in Eqs. (3.6)–(3.8)] A combination of mechanisms (I) and (II) or of mechanisms (I) and (III) could match the measurements. The rate for (I) was found to \(1.5 \pm 0.5\) times that of (II) or (III). Thus, proton interchange is only slightly faster than the carbon interchange. A later study by Saunders et al.\textsuperscript{98} using the double-labeled 2-propyl-[\textsuperscript{2}H,\textsuperscript{2}H,\textsuperscript{2}H,\textsuperscript{13}C] cation confirmed these results. Quenching of the D\textsubscript{3}-isopropyl ion by methycyclopentane and NMR analysis of the D\textsubscript{3}-propane product mixture gave preliminary results consistent with mechanisms (I) and (II) alone. Labeling experiments indicating the intermediacy of protonated cyclopropanes have also been performed by Lee and Woodcock\textsuperscript{99} and by Karabatsos et al.\textsuperscript{100}

\textit{Ab initio} theoretical calculations by Pople and co-workers\textsuperscript{101} and at the semiempirical level by Dewar and co-workers\textsuperscript{102,103} did not give consistent results. Subsequent \textit{ab initio} calculations (SCF level including electron correlation) by Lischka and Köhler\textsuperscript{104} are inconsistent with earlier \textit{ab initio} work. Their calculations have confirmed the stability of the isopropyl cation 2 and the instability of face-protonated cyclopropane 15. Edge-protonated cyclopropane 16 is found to be a saddle point on the
potential energy surface of lower energy (by 5 kcal mol$^{-1}$) than the corner-protonated species 17.

Subsequent high-level *ab initio* theoretical studies by Dewar et al.$^{105}$ (MP4SQ/6-31G* level) and by Koch, Schleyer, and co-workers$^{106}$ (MP2/6-311G** level) showed that both the corner-protonated and edge-protonated cyclopropane cations have unsymmetrical structure. Furthermore, the isopropyl cation was shown to be chiral$^{106–108}$ with a twisted structure of $C_2$ symmetry (18) [MP4/6-311G**/MP2/6-311G**+ZPE]. Structure 18 is the global minimum lying 7.2 kcal mol$^{-1}$ below the corner-protonated cyclopropane, which is also an energy minimum structure on the potential energy surface$^{107}$ and only about 2 kcal mol$^{-1}$ more stable than the edge-protonated species. Both $n$-propyl cations are saddle points.

Fornarini, Matîre, and co-workers$^{110}$ have recently used Fourier transform ion cyclotron resonance (FT–ICR) mass spectrometry assaying the multiphoton dissociation behavior (IR–MPD) of the $C_3H_7^+$ ion. This study has confirmed the conclusions of the computational results discussed above. The IR spectra recorded in solution and in a solid matrix display close resemblance to the spectral characteristics found by the IR–MPD study. Theoretical studies also indicated that the virtually free methyl rotation allows the interconversion of the two enantiomers of the isopropyl cation.

Intermolecular secondary–secondary hydride transfer between 2 and propane in SbF$_5$–SO$_2$ClF solution has been observed by Hogeveen and Gaasbeek.$^{111}$ The reaction was rapid on the NMR time scale, and a single peak was obtained from the two types of methyl groups down to at least $-100^\circ$C ($\Delta G^{\ddagger} \leq 6$ kcal mol$^{-1}$).

Similar scrambling has been documented in the case of secondary butyl 19 cation (see later discussion), and tert-pentyl cation 3 and 1-methylcyclopent-1-yl cation.$^{97,112}$ Subsequently, it was reported that even tert-butyl cation 1 undergoes such scrambling.$^{113}$ The tert-butyl cation 1 (60% $^{13}$C enriched at the cationic center) prepared from 2-choro-2-methylpropane in HSO$_3$F–SbF$_5$–SO$_2$ClF solution undergoes complete carbon scrambling in about 20 h at $+70^\circ$C (Figure 3.4). The most likely mechanism one can invoke for the scrambling process is the rearrangement through primary isobutyl cation 20 via the delocalized protonated methylcyclopropane intermediate (or transition state) 21 to the secondary butyl cation 19 (Scheme 3.1). The results seem to indicate a lower limit of $E_a \sim 30$ kcal mol$^{-1}$ for the
scrambling process, which could correspond to the energy between tert-butyl (1) and primary isobutyl (20) cations.

Saunders and co-workers have recently reported results strongly supporting the protonated cyclopropane intermediate in the isotope scrambling process. They found no isomerization of the 2-butyl-1,2-\(^{13}\)C\(_2\) cation (19a) at \(-78^\circ\)C, whereas the isotopomer 2-butyl-2,3-\(^{13}\)C\(_2\) cation (19b) showed rapid formation of all other isotopomers except 19a (Scheme 3.2). These results are consistent with the involvement of protonated cyclopropane with the interchange of either C(1) and C(2) or C(3) and C(4) with the breaking of only the C(2)–C(3) bond.
Scheme 3.2

_Ab initio_ theoretical calculations for the 4-methylpent-2-yl cation by Fărcaşiu et al.\textsuperscript{115} have shown both a distorted 1-protonated 1,1,2-trimethylcyclopropane and the open cation to be energy minima along the reaction coordinate at the B3LYP/6-31G** level. In contrast, only the protonated cyclopropane was found to be an energy minimum in the MP2/6-31G** optimization. Whereas the open cation was a transition structure at this level, a coupled cluster geometry optimization (CCSG/6-31G**) showed that the open ion is also a true energy minimum.

Infrared and Raman spectra of alkyl cations give valuable information of their structures (Table 3.4).\textsuperscript{71–73} The Raman spectroscopic data provide strong evidence that tert-butyl cation in Magic Acid solution prefers a conformation leading to overall $C_{3v}$ point group symmetry (Table 3.4 and Figure 3.5). Thus the $(\text{CH}_3)_3C^+$ ion exists in these solutions with a planar carbon skeleton and with one hydrogen atom of each CH$_3$ group above the plane. The other two hydrogen atoms are arranged symmetrically below the $^+\text{C}_3$ plane to the right and left of the C$_3$ axis. Raman spectra observed for the tert-pentyl cation, the pentamethylethyl cation, and the tetramethylethyl cation also show similar structures. The Raman spectroscopic studies thus provide, in addition to $^{13}$C NMR data, direct evidence for the planar carbenium center of alkyl cations.

The gas-phase infrared spectrum of the tert-butyl cation generated from tert-butyl chloride by a high voltage discharged in a pulsed supersonic expansion has recently been reported by Duncan and co-workers.\textsuperscript{116} The infrared photodissociation spectrum measured by means of argon tagging matches those predicted for the $C_1$ or $C_s$ geometries and differs significantly from those calculated for isomeric C$_4$H$_9^+$ cations (methyl-bridged and proton-bridged 2-butyl cations). Despite the significantly differing conditions, the band positions of the gas-phase spectrum and those determined by Olah et al.\textsuperscript{71} in superacid solution show remarkable similarity (Table 3.5). A significant difference is the resolution of the band at 1290 cm$^{-1}$ into a triplet.

Evidence for planarity or near planarity of the \textit{sp}$_2$ center of trivalent alkyl cations thus comes from the combined results of NMR ($^1$H and $^{13}$C), IR, and Raman spectroscopy.\textsuperscript{71–73,97}

In the electronic spectra (UV), alkyl cations in HSO$_3$F–SbF$_5$ at $-60^\circ$C show no absorption maxima above 210 nm.\textsuperscript{74}

X-ray photoelectron (ESCA) spectra of carbenium ions have also been obtained in frozen superacid solutions, generally in SbF$_5$–SO$_2$ solution or as isolated salts. Sulfur dioxide was subsequently removed by the usual freeze–thaw procedure. A thin layer of the viscous SbF$_5$ solution was deposited on the precooled sample holder, in a dry nitrogen

⁺IR frequency.
⁻Calculated.
atmosphere. The spectra were recorded at liquid nitrogen temperature.\textsuperscript{117} The photoelectron spectrum of tert-butyl cation \( \text{I} \) is shown in Figure 3.6. The lower traces in Figure 3.6 represent the results given by a curve resolver. The peak area ratio is close to 1:3.

The experimental carbon 1s binding energy difference (3.9 eV) between the carbenium ion center and the remaining three carbon atoms is in the limit of that predicted by \textit{ab initio} calculation (4.45 eV). Comparable results were obtained for the tert-pentyl cation (\( \Delta E_{b-C-C} = 4 \pm 0.2 \) eV).

Attempts have been made to prepare sterically highly crowded tertiary cations (see later discussion). The possibly most hindered trialkylmethyl cation, the tris(1-adamantyl)methyl ion \( \text{22} \), has been prepared from the corresponding chloride\textsuperscript{118} [Eq. (3.9)]. Proton loss is not favored in this case because this would lead to the formation of a bridgehead alkene. Consequently, cation \( \text{22} \) could be observed as a persistent, long-lived cation.

\textsuperscript{a}Only major absorption bands are given.
Yannoni, Myhre, and co-workers applied nutation NMR spectroscopy to determine the geometry of the tert-butyl cation using double $^{13}$C-labeled isotopomers at 77 K. The central carbon–methyl carbon bond distance was found to be 1.46–1.47 Å—that is, almost 0.1 Å shorter than the usual single-bond value. This bond length is in close agreement with the 1.457–1.459 Å found by Schleyer, Koch, and co-workers at the MP2(full)/6-31G** level. In this study, three forms of the tert-butyl cation (Cs, C3h, and C3v) were calculated and compared. The Cs form was found to be more stable than C3h by only 0.1 kcal mol$^{-1}$ [MP4sdq/6-31G**//MP2(full)/6-31G**], but after correction for zero-point energy the order reverses. This indicates that the potential energy surface of 1 is extremely flat. In contrast, structure C3v is 1.1 kcal mol$^{-1}$ higher in energy than C3h.

According to the X-ray crystal structure analysis of the tert-butyl cation (Sb$_2$F$_{11}^-$ salt) determined by Hollenstein and Laube, the average bond distance is 1.442 Å, the C–C–C bond angle is 120°, and the carbon skeleton has approximate D$_{3h}$ symmetry. Kato and Reed have recently used methyl carboranes [Me(CHB$_{11}$Me$_5$X$_6$), X = Cl, Br] to generate tertiary carbocations, including the tert-butyl and tert-pentyl cations, and determined their X-ray crystal structure. The tert-butyl cation is planar within experimental error (sum of bond angles = 360°), and the C–C bond distances are 1.429, 1.438, and 1.459 Å. As observed in both studies, the shorter C–C bond distances reflect partial double-bond character from substantial C–H hyperconjugation. In the tert-pentyl cation 3, a dihedral angle of 25.8° was...

Figure 3.6. Carbon 1s photoelectron spectrum of tert-butyl cation 1.
detected between the carbocation plane and the C(2)–C(3)–C(4) plane. This shows the near absence of C–C hyperconjugation, which was, however, suggested to exist by calculation having the C(2)–C(3)–C(4) plane aligned (parallel) with the vacant p orbital.\textsuperscript{124}

A recent computational study by Olah, Prakash, and Rasul (\textit{ab initio} methods at the MP2/cc-pVTZ level) has also shown that the structure of the tert-pentyl cation is stabilized by both C–C and C–H hyperconjugations.\textsuperscript{125} Both structures 23 and 24 have been found to be minima on the potential energy surface, and they are very close energetically (structure 23 is more stable by a mere 0.5 kcal mol\textsuperscript{-1}). Their interconversion has a kinetic barrier of only 1.5 kcal mol\textsuperscript{-1}. The calculated average \( ^{13}\text{C} \) NMR shift value of the cationic center (\( ^{13}\text{C} 334.6 \), GIAO-MP2 method) matches extremely well with both the experimental value (\( ^{13}\text{C} 335.4 \))\textsuperscript{95} and that calculated by Schleyer \textit{et al.} (\( ^{13}\text{C} 335.7 \), IGLO method).\textsuperscript{124}

\text{Me} & \quad \text{Me} \\
\text{Me} & \quad \text{Me}
\end{align*}
\]

24

3.4.1.3. \textit{Preparation from Other Precursors.} Alkyl cations can be formed not only from halide precursors (the earlier investigation of generation from alkyl fluorides was later extended to alkyl chlorides, bromides, and even iodides) but also from alkenes in superacids like HF–SbF\textsubscript{5} [Eq. (3.10)].

\[
R\text{CH}=	ext{CH}_2 + \text{HSO}_3\text{F}\cdot\text{SbF}_5 \rightarrow R\text{CH}--\text{CH}_3 
\]

(3.10)

Tertiary and reactive secondary alcohols in superacids like HSO\textsubscript{3}F–SbF\textsubscript{5} (Magic Acid), HSO\textsubscript{3}F, and SbF\textsubscript{5}–SO\textsubscript{2}–SO\textsubscript{2}ClF also ionize to the corresponding carbocations.\textsuperscript{126} The generation of alkyl cations from alcohols indicates the great advantages of increasing acidity and of using acid systems with low freezing points. Deno showed that the use of sulfuric acid and oleum results in formation of cyclized allylic ions from simple aliphatic alcohols.\textsuperscript{88} With the use of extremely strong acid, HSO\textsubscript{3}F–SbF\textsubscript{5}, tertiary and many secondary alcohols can be ionized to the corresponding alkyl cations [Eq. (3.11)].

\[
(\text{CH}_3)_3\text{COH} + \text{HSO}_3\text{F}\cdot\text{SbF}_5 \rightarrow (\text{CH}_3)_3\text{C}^+ 
\]

(3.11)

Primary and less reactive secondary alcohols are protonated in HSO\textsubscript{3}F–SbF\textsubscript{5} solution at low temperature (\(-60^\circ\text{C}\)) and show very slow reaction rates\textsuperscript{127} [Eqs. (3.12)
Temperature-dependence studies of the NMR spectra of protonated alcohols from $-60$ to $+60^\circ$C allow the kinetic of dehydration to be followed$^{128}$ [Eq. (3.14)].

\[
\begin{align*}
\text{CH}_3\text{CH}_2\text{CH}_2\text{OH} & \xrightarrow{\text{HSO}_3\text{F}^-\text{SbF}_5} \text{CH}_3\text{CH}_2\text{CH}_2\text{O}^\text{+}H_2 \quad (3.12) \\
\text{CH}_3\text{C}=\text{CH}-\text{CH}_3 & \xrightarrow{\text{HSO}_3\text{F}^-\text{SbF}_5} \text{CH}_3\text{C}=\text{CH}-\text{CH}_3 \quad (3.13)
\end{align*}
\]

Antimony pentafluoride itself (neat or in SO$_2$ or SO$_2$ClF solution) also ionizes alcohols to form alkyl carbocations [Eq. (3.15)].

\[
\begin{align*}
\text{R}^-\text{OH} & \xrightarrow{\text{SbF}_5\text{SO}_2} \text{R}^+\text{SbF}_5\text{OH}^- \quad (3.15)
\end{align*}
\]

To overcome difficulties and achieve ionization of primary (and less reactive secondary) alcohols at low temperatures, it was found, in some cases, that it is advantageous to convert them to the corresponding haloformates or halosulfites with carbonyl halides [Eq. (3.16)] or thionyl halides [Eq. (3.17)]. These, in turn, ionize readily in SbF$_5$–SO$_2$ solution and lose CO$_2$ or SO$_2$.$^{129}$

\[
\begin{align*}
\text{ROH} & \xrightarrow{\text{COX}_2} \text{ROCOX} \quad (3.16) \\
\text{ROH} & \xrightarrow{\text{SOX}_2} \text{ROSOX} \quad (3.17)
\end{align*}
\]

Sterically highly crowded tertiary cations have long eluded characterization. In an early hydrolysis study of tris-(tert)-butylmethyl para-nitrobenzoate, Bartlett and Stiles$^{130}$ reported the formation of a C$_{13}$ alkene formed as a result of repeated successive alkyl migrations. Under superacid conditions, tris(tert-butyl)methanol gave a mixture of equilibrating cations formed by a cleavage mechanism.$^{131}$ The secondary bis(1-adamantyl)methyl cation $25a$, in turn, undergoes fast rearrangement to yield a set of equilibrating 4-(1-adamantyl)-3-homoadamantyl cations.$^{132}$ However, tertiary ions
[methyl-, ethyl-, and phenyl-bis(1-adamantyl)methyl cations 25b–25d], with the exception of the tert-butyl-bis(1-adamantyl)methyl cation (25e), could be prepared and characterized under superacidic conditions.\textsuperscript{132}

\[ R = \begin{array}{c} \text{Me} \\ \text{Et} \\ \text{Ph} \\ \text{tert-Bu} \end{array} \]

Aliphatic ethers are protonated in strong acids, at low temperatures; the exchange rates of the acidic proton are slow enough to permit direct observation by NMR spectroscopy.\textsuperscript{133} Temperature-dependent NMR spectral studies allow us again to follow the kinetics of ether cleavage to form alkyl cations [Eq. (3.18)].

\[ \begin{array}{c} \text{CH}_3\text{OCH}_2\text{CH}_2\text{CH}_2\text{CH}_3 \\ \text{HSO}_3\text{F–SbF}_5 \end{array} \xrightarrow{-60^\circ\text{C}} \begin{array}{c} \text{CH}_3\text{OCH}_2\text{CH}_2\text{CH}_2\text{CH}_3 \\ \text{I} \\ \text{H} \\ \text{CH}_3\text{OH}_2 \\ [\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2] \end{array} \xrightarrow{\text{rearrangement}} \text{(CH}_3\text{)_3C}^+ \]

(3.18)

Superacids such as HSO\textsubscript{3}F–SbF\textsubscript{5} also act as very efficient hydrogen-abstraction agents, allowing the generation of carbocations from saturated hydrocarbons\textsuperscript{134} [Eq. (3.19)].

\[ \begin{array}{c} \text{CH}_3\text{CH} \rightarrow \text{CH}_3 \\ \text{I} \\ \text{CH}_3 \end{array} \text{HSO}_3\text{F–SbF}_5 \xrightarrow{\text{SO}_2\text{ClF}} \text{(CH}_3\text{)_3C}^+ \]

(3.19)

Alkyl cations can also be generated by decarbonylation of tertiary acylium ions, like the pivaloyl cation 26 [Eq. (3.20)].\textsuperscript{91} This reaction corresponds to the reverse of Koch–Haaf acid synthesis, which is known to involve carbocation intermediates. Indeed the reaction of the tert-butyl cation with carbon monoxide gives the pivaloyl cation.\textsuperscript{91,135}

\[ \begin{array}{c} \text{(CH}_3\text{)_3CCOF} \end{array} \xrightarrow{\text{SbF}_5} \text{[(CH}_3\text{)_3CCO]}^\text{+} \text{SbF}_6^- \xrightarrow{\Delta} \text{(CH}_3\text{)_3C}^+ + \text{CO} \]

(3.20)

Protonation and ionization of mercaptans (thiols) and thioethers (sulfides) have been similarly studied. Thiols and sulfides can also be used, similar to their oxygen analogs, as precursors for alkyl cations\textsuperscript{136} [Eq. (3.21)]. Ionization with SbF\textsubscript{5}-type superacids generally necessitates somewhat more forcing conditions (higher temperatures). Alkyl thiohaloformates also form alkyl cations via fragmentative
ionization\textsuperscript{137} [Eq. (3.22)].

\[
RSH + \text{SbF}_5 \text{ or HF-SbF}_5 \text{ or HSO}_3F-SbF_5 \rightarrow R^+Y^- \quad (3.21)
\]

\[
RSCOX + \text{SbF}_5-SO_2Cl \rightarrow R^+ \text{SbF}_5X^- + \text{COS} \quad (3.22)
\]

Amines also can be used as precursors for the generation of alkyl cations. The classic method of deaminative formation of carbocations involves some type of diazotation reaction producing an equimolar amount of water [Eq. (3.23)].

\[
\text{RNH}_2 + \text{HNO}_2 \rightarrow [\text{RN}_2^+] \rightarrow R^+ + N_2 \quad (3.23)
\]

Newer methods overcome this difficulty. The corresponding sulfinylamine or isocyanate is first prepared and then reacted with stable nitrosonium salts to give the corresponding carbocations\textsuperscript{138} [Eqs. (3.24) and (3.25)].

\[
\text{RNH}_2 + \text{SOCl}_2 \rightarrow \text{RNSO} \rightarrow R^+ \text{SbF}_6^- + N_2 + \text{SO}_2 \quad (3.24)
\]

\[
\text{RNH}_2 + \text{COCl}_2 \rightarrow \text{RNCO} \rightarrow R^+ \text{SbF}_6^- + N_2 + \text{CO}_2 \quad (3.25)
\]

Lambert et al.\textsuperscript{139} generated the $\beta$-triethylsilyl-substituted carbocation 27 reacting solvated triethylsilylium ion with 1,1,-diphenylethylene [Eq. (3.26)]. $\beta$-Silyl-substituted carbocations are of high interest because of the $\beta$-effect, that is, the ability of a silicon atom to stabilize a nonadjacent positive charge of a carbocationic center via hyperconjugation. Results have been summarized in reviews.\textsuperscript{140–142}

\[
[\text{Et}_3\text{Si}^+\text{C}_6\text{H}_6\text{B(C}_6\text{F}_5)_4]^+ + \text{Ph}_2\text{C}=\text{CH}_2 \rightarrow \text{Et}_3\text{Si}^+ \quad (3.26)
\]

The resonance of the cationic carbon ($\delta^{13}$C 225.4) is definitive for the cation structure 27a. The single $^{29}$Si shift ($\delta$ 46.2) is of higher frequency than neutral tetrahedral silicon, indicating that silicon bears some positive charge, that is, a small contribution from resonance structure 27b. The Bu$_3$GeCH$_2$C$^+$Ph$_2$ analog, in turn, showed increased hyperconjugation. No evidence was found for an Si-bridging structure.
3.4.1.4. Observation in Different Superacids. Whereas antimony pentfluoride-containing superacids (such as HF–SbF$_5$, H$_2$SO$_3$–SbF$_5$, CF$_3$SO$_3$H–SbF$_5$, etc.) are the preferred solvents for obtaining alkyl cations, other nonoxidizing superacids such as HF–BF$_3$ and HF–TaF$_5$ can also, on occasion, be used successfully. The stability of carbocations in these solvents is generally somewhat lower.

3.4.2. Cycloalkyl Cations

Tertiary cycloalkyl cations, such as the 1-methylcyclopent-1-yl cation 28, show high stability in strong acid solutions. This ion can be obtained from a variety of precursors (Figure 3.7). It is noteworthy to mention that not only cyclopentyl- but also cyclohexyl-type precursors give 1-methylcyclopent-1-yl cation 28. This indicates that the cyclopentyl cation has higher stability, which causes isomerization of the secondary cyclohexyl cation to the tertiary methycyclopentyl ion.

The methylcyclopentyl cation 28 undergoes both carbon and hydrogen scrambling. An activation energy of $15.4 \pm 0.5$ kcal mol$^{-1}$ was measured for a process that interchanges $\alpha$ and $\beta$ hydrogens in 28. Above 110°C, coalescence to a single peak was observed in the $^1$H NMR spectrum of 28. An activation energy barrier of $18.2 \pm 0.1$ kcal mol$^{-1}$ was found for the methyl and ring hydrogen interchange. The

![Figure 3.7. Preparation of 1-methylcyclopent-1-yl cation 28 from various precursors. Reaction conditions: (a) H$_2$SO$_3$–SbF$_5$, (b) SbF$_5$–SO$_2$, (c) HF–SbF$_5$–SO$_2$.](image)
protonated cyclopropane intermediate 30 required for the process (Scheme 3.3) might undergo an additional reversible ring opening to secondary cyclohexyl cation 32. To investigate this possibility, Saunders and Rosenfeld measured deuterium and carbon scrambling rates simultaneously using a mixture containing $^{13}$C- and deuterium-labeled methyl groups in methylcyclopentyl cation 28. The two observed rates were related in exactly the manner predicted if the protonated bicyclohexane 31 opens to 32 more rapidly than it returns to 30 via a corner-to-corner hydrogen shift.

A recent X-ray characterization of the cyclopentyl cation 33 generated with methyl carboranes has shown a perfect planar structure around the carbocation center (bond angles: CH$_3$–C$^+$–CH$_2$ = 124.9° and 125.2°, CH$_2$–C$^+$–CH$_2$ = 109.9°; bond distances: CH$_3$–C$^+$ = 1.46 Å, CH$_2$–C$^+$ = 1.45 Å).

The cyclopentyl cation 33 shows in its proton NMR spectrum in SbF$_5$–SO$_2$ClF solution, even at $-150^\circ$C, only a single absorption line at $\delta^1$H 4.75. This observation indicates a completely degenerate ion with a very low barrier to the secondary–secondary hydrogen shift (see Section 3.5.2.1). Although stable secondary cyclohexyl cation 32 is unknown under long-lived stable ion conditions, a static secondary cyclohexyl cation 34 with an $\alpha$-spiro-cyclopropyl group (spiro[2.5]oct-4-yl cation) has been prepared and studied by various routes (Scheme 3.4). However, this ion derives its stability by substantially delocalizing its positive charge into the neighboring cyclopropyl group (i.e., it is also a cyclopropylcarbinyl cation). The bisected nature of the cyclopropyl group is indicated by a single $^{13}$C NMR signal for the cyclopropyl methylene group. Ion 34 is stable up to $-10^\circ$C, where it rearranges to the equilibrating bicyclo[3.3.0]oct-1-yl cation 35.

Sorensen and co-workers have prepared tertiary cycloalkyl cations of different ring sizes, $n$ = 4 (small ring), $n$ = 5–7 (common rings), $n$ = 8–11 (medium rings),
Scheme 3.4

\( n = 12–20 \) (large rings). These ions were in general found to undergo ring expansion or contraction reactions, often in multiple or repetitive steps as shown in the following sequence. At very low temperature, some of these cycloalkyl cations \( (n = 8–11) \) show \( \mu \)-hydrido bridging (see Section 3.5.2.6).

\[
\begin{align*}
4^+&-\text{Pr} &\rightarrow& 5^+&-\text{Et} + 6^+&-\text{Me} \\
5^+&-\text{Et} &\rightarrow& 6^+&-\text{Me} \\
7^+&-\text{Pr} &\rightarrow& 6^+&-\text{Bu} \\
8^+&-\text{Et} &\rightarrow& 6^+&-\text{Bu} \\
9^+&-\text{Me} &\rightarrow& 8^+&-\text{Et} + 7^+&-\text{Pr} + 6^+&-\text{Bu} \\
10^+&-\text{Me} &\rightarrow& 6^+&-\text{Pen} \\
10^+&-\text{Et} &\leftrightarrow& 11^+&-\text{Me} \\
11^+&-\text{Me} &\leftrightarrow& 10^+&-\text{Et} &\leftrightarrow& 6^+&-\text{Hex} \\
10^+&-\text{Pr} &\rightarrow& 12^+&-\text{Me} + 6^+&-\text{Hept} \\
11^+&-\text{Et} &\rightarrow& 12^+&-\text{Me} + 10^+&-\text{Pr} \\
12^+&-\text{Pr} &\rightarrow& 13^+&-\text{Et} \\
13^+&-\text{Et} &\rightarrow& 14^+&-\text{Me} \\
14^+&-\text{Et} &\rightarrow& 15^+&-\text{Me} \\
12^+&-\text{R} &\rightarrow& \text{ring expansion}
\end{align*}
\]

Tertiary (2-propyl)cycloalkyl cations were prepared from the corresponding alcohols\(^{151}\) using the technique developed by Saunders.\(^{46}\) The ions undergo fast nondegenerate 1,2-hydride shifts, and the direction of equilibria investigated by \(^{13}\)C NMR spectroscopy was found to depend on the ring size. For the cyclopentyl derivative, the cyclopentyl cation \( 36b \) is more stable [Eq. (3.27)], whereas for the cyclohexyl derivative the cyclohexyl cation \( 37a \) is the more stable structure [Eq. (3.28)]. Calculations [MP2/6-31G(d) level] found three minimum energy structures for the cyclohexyl derivative, including two conformers of \( 37b \): one with the empty \( p \) orbital occupying an equatorial-like position, the other with an axial-like position. In both structures, one
of the methyl groups is oriented for C−C hyperconjugation with the empty $p$-orbital of C\(^+\). Similar conformations called hyperconjomers were also calculated for the 1-methylcyclohexyl cation.\(^{152}\)

\[ \text{36a} \xleftrightarrow{} \text{36b} \]

\[ \text{37a} \xleftrightarrow{} \text{37b} \]

A series of aryl-substituted cycloalkyl cations 38 and 39 and other aryl-substituted cyclic systems (40, 41, 42) have been studied in connection with the application of the tool of increasing electron demand.\(^{67,153–156}\)

\[ n = 0–2 \quad X = \text{H, 4-Me, 4-MeO, 4-Br, 4-Cl, 4-F, 3-CF}_3, 4-CF_3, 3,5-(CF}_3) \_2, \text{etc.} \]

\[ n = 1, 2 \]

The X-ray crystal structure of the 2-phenyladamant-2-yl cation (43) determined by Laube and Hollenstein\(^{157}\) shows remarkable features. Namely, the displacement of the C(2) bridge by 7.8°, the additional bending of the phenyl ring out of plane by 5.6°, and a slight pyramidalization of $\Delta = 0.049$ Å (pyramidalization $\Delta$: distance of a tricoordinate atom from the plane through its neighbors). Furthermore, the C\(_{\alpha}\)−C\(_{\beta}\) bond distance is shorter compared with the reference value (1.45 Å versus 1.51 Å), whereas the C\(_{\beta}\)−C\(_{\gamma}\) bond is elongated (1.58 Å versus 1.53 Å). These features are consistent with the C−C hyperconjugation between the cation center and the C\(_{\beta}\)−C\(_{\gamma}\) bond.
The direct observation of the cyclopropyl cation $44$ has evaded all attempts, owing to its facile ring opening to the energetically more favorable allyl cation $45$ [Eq. (3.29)].

$$
\begin{align*}
\text{H} & \quad \rightarrow \\
44 & \quad 45
\end{align*}
$$

Many cyclopropyl cation precursors indeed readily rearrange to allyl cations under stable ion conditions. However, a distinct cyclopropyl cation $46$ showing a significant $2\pi$ aromatic nature has been prepared by the ionization of 11-methyl-11-bromotricyclo[4.4.1.0$^{1,6}$]undecane in SbF$_5$–SO$_2$ClF solution at $-120^\circ$C [Eq. (3.30)].

$$
\begin{align*}
\text{H}_3\text{C}\text{Br} & \quad \text{SbF}_5\text{–SO}_2\text{ClF} \\
& \quad -120^\circ\text{C} \\
46 & \quad \text{SbF}_5\text{–SO}_2\text{ClF} \\
& \quad -120^\circ\text{C}
\end{align*}
$$

The direct observation of ion $46$ is of particular interest in that it clearly does not involve a significantly opened cyclopropane ring, which could lead to the formation of an allylic cation. Thus, it must be considered as a bent cyclopropyl cation. It is, however, clear that the C$_1$–C$_6$ $\sigma$-bond must to some degree interact with the empty $p$ orbital at C$_{11}$ and that “homoconjugation” between them becomes the important factor in stabilizing such a “bent” cyclopropyl species.

The parent secondary cyclobutyl cation $47$ undergoes threefold degenerate rearrangement via $\sigma$-bond delocalization involving nonclassical bicyclobutonium ion-like system (see Section 3.5.2.5). Similar behavior is also observed for the 1-methylcyclobutyl cation $48a$. The 1-phenylcyclobutyl cation $48b$, on the other hand, is a trivalent tertiary carbocation.

$$
\begin{align*}
47 & \quad 48 \\
\text{R} & \quad \text{R} = \text{Me} \quad \text{a} \\
& \quad \text{R} = \text{Ph} \quad \text{b}
\end{align*}
$$

### 3.4.3. Bridgehead Cations

Bredt’s rule in its original form excluded the possibility of carbocation formation at bridgehead positions of cycloalkanes. Indeed, bridgehead halides, such as apocamphyl chloride, proved extremely unreactive under hydrolysis conditions. However, 1-bromoadamantane very readily gives the bridgehead carboxylic acid under the usual conditions of Koch–Haaf acid synthesis. 1-Fluoromoadamantane is ionized in SbF$_5$ to give the stable bridgehead 1-adamantyl cation $49$ [Eq. (3.31)].
The proton NMR spectrum of the 1-adamantyl cation 49 in SbF$_5$ solution at 25°C consists of resonances at $\delta^1$H 5.40, 4.52, and 2.67 with peak areas of 3:6:6 (Figure 3.8a). The $^{13}$C NMR spectrum (Fig. 3.8b) shows the $\gamma$-carbons more deshielded than the $\beta$-carbon atoms, indicating strong C–C bond hyperconjugation with the empty $p$ orbital. The bridgehead 1-adamantyl cation 49 can also be prepared

Figure 3.8. (a) $^1$H NMR spectrum of the 1-adamantyl cation at 60 MHz, 100 MHz, and 250 MHz; (b) Fourier-transform $^{13}$C NMR spectrum of the 1-adamantyl cation (in HSO$_3$F–SbF$_5$).
from 2-adamantyl as well as trimethylene norbornyl precursors\textsuperscript{182} [Eq. (3.31)]. A subsequent solid-state\textsuperscript{13}C NMR spectral study of 1-adamantyl hexafluoroantimonate salt using magic-angle spinning and cross-polarization techniques indicates similarities between solid-state spectra and previously obtained solution spectra.\textsuperscript{182} The 1-adamantyl cation \textsuperscript{49} has been calculated to be more stable by 11 kcal mol\textsuperscript{-1} than the 2-adamantyl cation.\textsuperscript{183} The IR spectrum of cation \textsuperscript{49} was reported\textsuperscript{184} and found to be in reasonably good agreement with the theoretical spectrum.\textsuperscript{183} 

Several methyl-substituted bridgehead adamantyl cations \textsuperscript{50} have been prepared and characterized. The X-ray structure of the 3,5,7-trimethyladamant-1-yl cation has been determined by Laube.\textsuperscript{185,186} The C\textsubscript{α}–C\textsubscript{β} bond distance (1.439 Å) is slightly shorter than, whereas the C\textsubscript{β}–C\textsubscript{γ} bond length (1.612 Å) is somewhat longer than, the corresponding reference value (1.502 Å and 1.538 Å, respectively). This supports the C–C hyperconjugation in the bridgehead adamantyl cation. The \textit{sp}\textsuperscript{2} carbocationic center has a pyramidal structure with a pyramidalization value \(\Delta = 0.212 \text{ Å}\). The unusual geometry of the cation center is also indicated by the C\textsubscript{β}–C\textsubscript{α}–C\textsubscript{β} and C\textsubscript{α}–C\textsubscript{β}–C\textsubscript{γ} bond angles (117.9° and 99.7°, respectively). The bridgehead homoadamantyl cation \textsuperscript{51} has been obtained\textsuperscript{187} from both adamantylcarbinyl and homoadamantyl precursors [Eq. (3.32)].

\[
\begin{align*}
\text{R}_2\text{R}_1^+ + \text{X} = \text{OH, Cl, Br} \\
\text{CH}_2\text{Cl} & \rightarrow & + & \rightarrow & + \\
\text{50} & & \text{51} & & \text{52} \\
\alpha & & \beta & & \gamma \\
\text{R} & = & \text{CH}_3, \text{R}_1, \text{R}_2 & = & \text{H} \\
\text{R}, \text{R}_1 & = & \text{CH}_3, \text{R}_2 & = & \text{H} \\
\text{R}, \text{R}_1 & = & \text{CH}_3, \text{R}_2 & = & \text{CH}_3 \\
\end{align*}
\]

Bridgehead bicyclo[4.4.0]decyl, bicyclo[4.3.0]nonyl, and bicyclo[3.3.0]octyl cations are found to be rapid equilibrating ions (see Section 3.5.2.1).\textsuperscript{188} The isomeric bridgehead congressane (diamantane) cations \textsuperscript{52} and \textsuperscript{53} have been prepared and observed.\textsuperscript{182} The diamant-4-yl cation \textsuperscript{52} rapidly rearranges to the diamant-1-yl cation \textsuperscript{53} at \(-60^\circ\text{C}\), possibly through intermolecular hydride shifts. Bridgehead bicyclo[3.3.3]undec-1-yl cation \textsuperscript{54} has also been observed by \textit{1}H and \textit{13}C NMR spectroscopy.\textsuperscript{189}
Olah, Prakash, and Stephenson\textsuperscript{190} prepared isomeric triamantyl cations. Protolytic ionization of the parent triamantane yielded a mixture of the triamant-2-yl and triamant-3-yl cations 55 and 56, respectively. The two cations, however, could be cleanly generated from 2- and 3-triamantanol, respectively, in SbF$_5$–SO$_2$ClF at $-80^\circ$C. Ionization of 9-triamantanol, in turn, gave exclusively bridgehead cation 56.

Fokin, Schreiner, and co-workers\textsuperscript{191} have calculated the stability of tertiary diamondoidyl cations relative to the 1-adamantyl cation (B3LYP/6-31G* level). The relative stabilities were found to increase continuously with cage size: The penta- and hexamantyl cations are about 10 kcal mol$^{-1}$ more stable than the 1-adamantyl cation. Furthermore, when isomeric cations are compared, the position of the cationic center also affects stabilities. Namely, the closer the cationic carbon to the geometrical center of the molecule, the higher the stability. For example, 4-diadamantyl cation is more stable than 1-diadamantyl cation (3 kcal mol$^{-1}$). Also illustrative is the comparison of the least and most stable tetramantyl cations: Cation 57 is less stable by 4.5 kcal mol$^{-1}$ than cation 58, and the distances of the cationic centers to the geometrical center are, respectively, 3.309 and 1.282 Å.

Bridgehead bicyclo[2.2.1]hept-1-yl cation (1-norbornyl cation) has not yet been directly observed; 1-chloronorbornane yields the stable 2-norbornyl cation in SbF$_5$–SO$_2$ solution.\textsuperscript{192} Thus, ionization to the bridgehead carbocation must be followed by a fast shift of hydrogen from C(1) to C(2) (either intramolecular or intermolecular), the driving force for which is obviously the tendency to relieve strain in the carbocation.

Starting with dodecahedrane or substituted derivatives, Olah, Prakash, Paquette, and coworkers prepared dodecahedryl cation 59 under superacid conditions\textsuperscript{193,194}.
The $^{13}$C NMR spectrum showed six absorptions [the most deshielded at $\delta^{13}C$ 363.9 (s)] clearly indicating that dodecahedryl cation 59 is a static ion. It showed no tendency to undergo degenerate hydrogen scrambling (no change in the $^1H$ NMR line shapes was observed up to 0°C). Upon standing in the superacid medium at $-50^0C$, cation 59 slowly and irreversibly transformed into dodecahedrane-1,16-diyl dication (see Section 3.4.12).

\vspace{1cm}

3.4.4. Cyclopropylmethyl Cations

Solvolytic studies of Roberts and Mazur$^{195}$ and Hart and Sandri$^{196}$ showed both the unusual stability of cyclopropylmethyl cations and the ease with which such ions rearrange. Cyclopropyl groups have a strong stabilizing effect on neighboring carbocation center by delocalizing charge through bent $\sigma$-bond. The direct observation$^{197}$ of a variety of cyclopropylmethyl cations in cyclic, acyclic, and polycyclic systems by NMR spectroscopy provides one of the clearest examples of delocalization of positive charge into a saturated system.$^{198,199}$

The first cyclopropylmethyl cation directly observed was the tricyclopropylmethyl cation 60 by Deno et al.$^{197}$ Its $^1H$ NMR spectrum in $H_2SO_4$ consists of a single sharp line at $\delta^1H$ 2.26.$^{200}$ In the 300-MHz $^1H$ NMR spectrum in $SbF_5$–$SO_2$ClF solution, however, the methine and methylene protons are well-resolved$^{201}$ (Figure 3.9).

Since then, a wide variety of cyclopropylmethyl cations have been prepared and studied by $^{13}$C and $^1H$ NMR spectroscopy.$^{201–203}$ These studies have led to the conclusion that cyclopropylmethyl cations adopt bisected geometry and are static in nature with varying degrees of charge delocalization into the cyclopropane ring. Most interesting of these ions is the dimethylcyclopropylmethyl cation 61 (Figure 3.10). The methyl groups are nonequivalent and show a $^1H$ NMR shift difference of 0.54 ppm. The energy difference between bisected and eclipsed structures is estimated to be 13.7 kcal mol$^{-1}$ (by temperature-dependent NMR studies)$^{204}$ and is quite close to the 12.3 kcal mol$^{-1}$ energy obtained by molecular orbital calculations at the minimal basis set STO-3G.$^{174}$

Previously discussed spiro[2.5]oct-4-yl cation 34$^{148}$ is also a cyclopropylmethyl cation with substantial positive-charge delocalization into the cyclopropyl group. Other representative cyclopropylmethyl cations that have been prepared in the
superacid media and characterized are cations $62, 63, 64, 65, 66, 67, 68$. 

Figure 3.9. $^1$H NMR spectrum (300 MHz) of the tricyclopropylmethyl cation in SbF$_5$–SO$_2$ClF at $-60^\circ$C.
Primary and secondary cyclobutylmethyl cations are nonclassical in nature and rearrange to thermodynamically more stable products (e.g., cyclopentyl cations). In search for a persistent cyclobutylmethyl cation, Prakash, Olah, and co-workers\textsuperscript{209,210} were able to prepare the more stabilized tertiary cyclobutyldicyclopropylmethyl cation 69 by ionizing the corresponding alcohol at $-90^\circ$C. Variable temperature $^{13}$C NMR studies and theoretical calculations showed that the ion is classical and exists preferentially in a bisected conformation at $-80^\circ$C with significant delocalization into the neighboring cyclopropyl rings (B3LYP/6-31G*).

Olah, Prakash, and co-workers\textsuperscript{211} generated and characterized the 2-substituted spirocyclopropane-norbornane cations 70 [Eq. (3.34)]. Cation 70c proved to be highly stable species, which is attributed to the superior stabilizing effect of the cyclopropyl groups. The methyl- and phenyl-substituted cations 70a and 70b rearranged to the corresponding allylic cations 71 even at slight warming [Eq. (3.34)]. $^{13}$C NMR chemical shift values support the observed order of stability: As the cationic center is increasingly stabilized by methyl to phenyl to cyclopropyl, the quaternary carbon is progressively less deshielded ($\delta^{13}$C 69.2, 61.2, and 58.8 for 70a, 70b, and 70c,

\[ \text{CH}_3 \text{bisected} \]

\[ \text{CH}_3 \text{eclipsed} \]

\[ \text{CH}_3 \text{CH}_3 \text{CH}_3 \text{CH}_3 + + + + \]

\[ \text{CH}_3 \text{CH}_3 \text{CH}_3 \text{CH}_3 \]

\[ \delta, \text{ppm} \]

\[ 4.0 \quad 3.0 \]

\[ \text{Figure 3.10.} \quad 100$\text{-MHz}$^{1}$H NMR spectrum of the dimethylcyclopropylmethyl cation. \]
respectively). A wide range of studies have indicated \textsuperscript{198,201,212–214} that a cyclopropyl group is equal or more effective than a phenyl group in stabilizing an adjacent carbocation center. Schleyer and co-workers\textsuperscript{215} found (orbital deletion procedure at HF/6-311G** level) that the hyperconjugation energy in the cyclopropylmethyl cation is as large as the conjugation effect of the allyl cation. Consequently, cyclopropane is just as effective as an electron donor as a C=C double bond. The parent secondary cation (70, $R = H$) could not be observed; only the corresponding rearranged allylic cation was obtained.\textsuperscript{149}

The cyclopropylmethyl cation has recently been generated in the gas phase from both homoallyl chloride and cyclopropylmethyl chloride and studied using collisional activated dissociation mass spectrometry.\textsuperscript{216} Interestingly, cyclobutyl chloride, which yields the cyclopropylmethyl cation in the condensed phase, gives a substantial amount of the bicyclobutonium ion in the gas phase.

In contrast to "classical" tertiary and secondary cyclopropylmethyl cations (showing substantial charge delocalization into the cyclopropane ring but maintaining its identity), primary cyclopropylmethyl cations show completely $\sigma$-delocalized nonclassical carbonium ion character (see Section 3.5.2.5). Also, some of the secondary cyclopropylmethyl cations undergo rapid degenerate equilibrium (see later discussion).

### 3.4.5. Alkenyl Cations

Many alkenyl cations have now been directly observed particularly by Deno, Richey and co-workers,\textsuperscript{88,217,218} Sorensen,\textsuperscript{219} Olah and co-workers,\textsuperscript{220–227} and Carpenter.\textsuperscript{228} Deno\textsuperscript{229} has reviewed the chemistry of these ions. Allylic cations particularly show great stability with generally insignificant 1,3-overlap, except in the case of cyclobutenyl cations\textsuperscript{230} (vide infra). Representative observed alkenyl cations are 72,\textsuperscript{229} 73,\textsuperscript{221–223} 74,\textsuperscript{221,222} 75,\textsuperscript{221,223} 76,\textsuperscript{223} and 77.\textsuperscript{226}
The formation of allyl cations from halocyclopropanes via ring opening of the unstable cyclopropyl cations also has been investigated\textsuperscript{159,161,162} [Eq. (3.35)].

\[ + \text{Cl} \quad \text{Cl} \quad \text{CH}_3 \quad \text{CH}_3 \quad \text{CH}_3 \quad \text{CH}_3 \quad \text{SbF}_5^{-} \quad \text{SO}_2 \]

\((3.35)\)

In fact, this approach has been used by Schleyer and coworkers to generate the parent allyl cation in superacid cryogenic matrix.\textsuperscript{231} Codeposition of cyclopropyl bromide and SbF\textsubscript{5} at 110 K resulted in a clean IR spectrum with the prominent signal at 1578 cm\textsuperscript{-1}. This was assigned to the asymmetric C−C−C allyl stretching vibration and is in good agreement with calculated values of 1592 cm\textsuperscript{-1} (MP2/6-31G\*) and 1558 cm\textsuperscript{-1} (CISD/6-31G**). A previous report for the allyl cation formed in zeolites and detected by \textsuperscript{13}C CP-MAS NMR was questioned on the basis of the lower than expected \textsuperscript{13}C NMR shift of \textsuperscript{6}\textsuperscript{13}C 218.\textsuperscript{232} A recent study by Duncan and co-workers (infrared photodissociation spectroscopy by means of rare gas tagging)\textsuperscript{233} has confirmed previous findings of the resonance-stabilized, charge-delocalized structure of \textit{C}_{2v} symmetry.\textsuperscript{164} The 2-propenyl cation has also been detected and was shown to have \textit{C}_{s} symmetry and a nearly linear C−C−C backbone with hyperconjugative stabilization by the methyl group. Schleyer and co-workers\textsuperscript{234} also detected the trans-1-methylallyl cation using the matrix isolation technique.

The 2-chloroallyl cation generated by matrix isolation has been studied by FT–IR spectroscopy and calculations [MP2(fc)/6-311G(d,p) level].\textsuperscript{235} Structure \textit{78} of \textit{C}_{s} symmetry with bridging chlorine, proposed earlier,\textsuperscript{162} was found to be less stable by 7.5 kcal mol\textsuperscript{-1} than cation \textit{79} of \textit{C}_{2v} symmetry and could not be found by spectroscopy. Furthermore, in contrast to 1- or 3-chloroallyl cations, the centrally positioned chlorine does not contribute to charge delocalization through back-donation as a consequence of the \(\pi\)-orbital noninteraction between the \(n\) electrons of Cl and the LUMO of the allyl cation.\textsuperscript{236}

\[ \begin{align*}
\text{Cl} & + \text{C} \equiv \text{C} \text{H} \\
\text{H} & \text{H} \text{H} \text{H} \text{H}
\end{align*} \]

\(\text{78}\)

\[ \begin{align*}
\text{H} & + \text{C} \equiv \text{C} \text{H} \\
\text{H} & \text{H} \text{H} \text{H} \text{H}
\end{align*} \]

\(\text{79}\)

Allyl cations \textit{80} and \textit{81} have been generated and studied by NMR spectroscopy.\textsuperscript{237} Although sterically crowded, cation \textit{80} proved to be surprisingly stable up to 80°C. The rotational barrier estimated on the basis of the coalescence temperature of the \textsuperscript{13}C NMR signals is 16.8 kcal mol\textsuperscript{-1}, in good agreement with the calculated value (MNDO, 16.5 kcal mol\textsuperscript{-1}). In contrast, the rotational barrier of cation \textit{81} was found to be less
than 5 kcal mol\(^{-1}\). This was attributed to the charge stabilizing effect of the adjacent cyclopropyl groups, resulting in an unsymmetrically charge-delocalized species.

Protonation of allenes also leads to allyl cations, allowing one to obtain ions—for example, the dimethylallyl and tetramethylallyl cations 82 [Eq. (3.36)]—that are otherwise difficult to generate from allylic precursors.\(^{238}\)

\[
\begin{align*}
\text{R} & \equiv \text{C} \equiv \text{C} \equiv \text{R} \\
\text{H}_3\text{C} & \quad \text{HSO}_3\text{F} \text{-SbF}_5 \text{-SO}_2\text{ClF} \\
\text{CH}_3 & \quad -70^\circ\text{C} \\
\text{R} = \text{H, CH}_3
\end{align*}
\]

(3.36)

### 3.4.6. Alkadienyl and Polyenyllic Cations

Deno, Richey, and their co-workers\(^{88}\) have observed a substantial number of alkadienyl cations. Sorensen\(^{239}\) has observed divinyl and trivinyl cations 83 and 84.

Alkadienyl cations such as the 1,3,5-trimethylheptadienyl cation 85 show great tendency to cyclize [Eq. (3.37)] and these reactions have been followed by NMR.\(^{240}\) Several novel fulvenes have been protonated to their corresponding dienyl cations\(^{241}\) (e.g., 86 and 87).

\[
\begin{align*}
\text{HSO}_3\text{F} \text{SbF}_5 & \quad -30^\circ\text{C} \\
\text{R} = \text{H, CH}_3
\end{align*}
\]

(3.37)
Sorensen and co-workers\textsuperscript{242} have studied the stereochemistry of ring closure of arylallyl cations to bicyclic trienyl cations. Similar studies on 1-phenylallyl cations have been carried out by Olah et al.\textsuperscript{225} Persistent polyenyllic cations generated upon incorporation of cinnamyl alcohols in zeolitic matrix have been identified on the basis of IR and UV–visible spectroscopy.\textsuperscript{243}

3.4.7. Arenium Ions

Cycloalkadienyl cations, particularly cyclohexadienyl cations (benzenium ions), the intermediate of electrophilic aromatic substitution, frequently show remarkable stability. Protonated arenes can be readily obtained from aromatic hydrocarbons\textsuperscript{244–251} in superacids and studied by \textsuperscript{1}H and \textsuperscript{13}C NMR spectroscopy.\textsuperscript{252,253} Olah et al.\textsuperscript{252} have even prepared and studied the parent benzenium ion (\(\text{C}_6\text{H}_7^+\)) \textsuperscript{88}. Representative \textsuperscript{1}H NMR spectra of benzenium\textsuperscript{253} and naphthalenium ions\textsuperscript{254,88 and 89} are shown in Figures 3.11 and 3.12, respectively.

Isomeric mono-, di-, tri-, tetra-, penta-, and hexaalkylbenzenium and halobenzenium ions have been observed.\textsuperscript{251,252,255} Alkylation, nitration, halogenation, and so on, of hexamethylbenzene give the related ions. Doering, Saunders, and co-workers\textsuperscript{256} have studied the dynamic NMR spectra of heptamethylbenzenenium ion \textsuperscript{90} (\(R = \text{Me}\)), and Fyfe and co-workers\textsuperscript{257} have obtained the solid-state \textsuperscript{13}C NMR spectrum.\textsuperscript{257}

Recent progress in experimental techniques allowed the isolation of various benzenium ions, including the parent ion \textsuperscript{88} as stable salts, which permitted their characterization by X-ray crystallography. Kochi and co-workers\textsuperscript{258} generated

\[ \text{C}_6\text{H}_7^+ \]

\[ \text{C}_6\text{H}_5\text{R}^+ \]

\[ \text{C}_6\text{H}_5\text{Cl}^+ \]

\[ \text{C}_6\text{H}_5\text{H}^+ \]

\[ \text{C}_6\text{H}_5\text{I}^+ \]

\[ \text{C}_6\text{H}_5\text{F}^+ \]

\[ \text{C}_6\text{H}_5\text{Br}^+ \]

\[ \text{C}_6\text{H}_5\text{Cl}^+ \]

\[ \text{C}_6\text{H}_5\text{F}^+ \]

\[ \text{C}_6\text{H}_5\text{Br}^+ \]

\[ \text{C}_6\text{H}_5\text{I}^+ \]

Figure 3.11. The 270-MHz \textsuperscript{1}H NMR spectrum of the “static” benzenium ion in HSO\textsubscript{3}F–SbF\textsubscript{5}–SO\textsubscript{2}ClF–SO\textsubscript{2}F\textsubscript{2} solution at \(-140^\circ\text{C}\).
the chlorohexamethylbenzenium cation \(90, \text{R} = \text{Cl}\) and isolated it as the hexachloroantimonate salt, whereas Reed et al.\textsuperscript{259,260} transformed benzene, toluene, meta-xylene, mesitylene, and penta- and hexamethylbenzene to the corresponding benzenium ions with carborane superacids \([H(C\text{B}_{11}H\text{R}_{5}X_6)], \text{R} = \text{H, Me; X} = \text{Cl, Br}\] and applied NMR spectroscopy, IR spectroscopy, and X-ray crystallography for characterization. According to Mulliken population analysis, the positive charge is delocalized onto the H atoms with the greatest partial charges on the hydrogens at the \(sp^3\) carbon. Crystallographic data show that the cyclohexadienyl resonance form is the best representation from the point of view of bond lengths as shown for meta-xylene ion \(91\). All bond angles are within 4° of the idealized value of 120°. The benzenium ion skeleton is essentially planar with a slight tilt of the protonated carbon the largest being 4.3° for the mesitylenium ion.

The Si-substituted \([\text{Et}_3\text{Si}(\text{C}_6\text{H}_4\text{Me})]^+\) cation was originally erroneously identified as being a silyl cation (silicenium ion, \(92\text{b}\))\textsuperscript{261} on the basis of a long Si–C\textsubscript{toluyl} bond distance of 2.18 Å. Calculated bond distances and bond angles (HP/6-31G* level)\textsuperscript{262} are in close agreement with those found experimentally. Similarly, there is a particularly good agreement between the observed (\(\delta^{29}\text{Si} 81.8\)) and calculated (\(\delta^{29}\text{Si} 82.1\)) \(^{29}\text{Si}\) NMR chemical shifts, in contrast with the calculated highly deshielded shift.
of 355.7 ppm of the still elusive Me₃Si⁺ ion. These observations indicate that the actual species is the \textit{para}-triethylsilyltoluenium ion \textit{92a} with contribution from the resonance form \textit{92b}. In a subsequent study, (IGLOII/B3LYP/6-31G*) chemical shift values of δ^{29}Si 79.7 and 79.8 for two isomeric forms of \textit{92a} were calculated, whereas the chemical shift for the silicenium ion \textit{92b} was computed to be δ^{29}Si 371.3.

![Diagram](image)

Novel bis-silylated arenium ions \textit{93} have been generated and characterized by Müller and co-workers. A single \textsuperscript{29}Si NMR signal with shift values (δ^{29}Si 19.1–25.6) close to those found for bis-β-silyl-substituted vinyl cations (δ^{29}Si 22–24) indicates in each case the formation of a symmetric species. The strongly deshielded \textit{ortho} and \textit{para} carbons (Δδ\textsubscript{13}C\textsubscript{ortho} = 28.9–39.6 and Δδ\textsubscript{13}C\textsubscript{para} = 21.6–35.1) relative to the starting silanes lend further evidence to the cation structure. Furthermore, the strong high-field shifts of the \textit{ipso} carbons (Δδ\textsubscript{13}C\textsubscript{ipso} = 36.5–49.4) relative to the precursors are indicative of the rehybridization of C\textsubscript{ipso} from sp\textsuperscript{2} to sp\textsuperscript{3}. The calculated structures of cations clearly show that these are arenium ions, and NMR shift calculations [GIAO/B3LYP/6-311G(d,p)//B3LYP/6-31G(d)+ZPE level] corroborate the validity of the structures.

![Diagram](image)

Lickiss and co-workers have synthesized and characterized the bis-silylated cation \textit{94}. Structural analysis of crystals isolated shows an almost symmetrical bridging of the phenyl ring [Si(1)–C\textsubscript{ipso} and Si(2)–C\textsubscript{ipso} distances = 2.104 and 2.021 Å, respectively]. In contrast to \textit{93} and other arenium ions that have alternating bond lengths attributed to the cyclohexadienyl resonance structure (long C\textsubscript{ipso}–C\textsubscript{ortho} and C\textsubscript{ortho}–C\textsubscript{meta}, and short C\textsubscript{meta}–C\textsubscript{para} bonds), the bond distances of cation \textit{94} are rather similar (C\textsubscript{ipso}–C\textsubscript{ortho} = 1.39 and 1.40 Å, C\textsubscript{ortho}–C\textsubscript{meta} = 1.36 and 1.37 Å, C\textsubscript{meta}–C\textsubscript{para} = 1.35 and 1.37 Å). Furthermore, calculations have shown [B3LYP/6-31G(d)] that the positive charge is predominantly on the four-membered ring. The authors
concluded that the 1,3-phenyl-bridging structure 94b is a better description for the cation than the bis-silylated benzenium ion 94a.

\[ \text{Si}(\text{Me}_3\text{Si})_2\text{C} \quad \text{Si}(\text{Me}_3\text{Si})_2\text{C} + \]

94

The novel arenium ion 95 was synthesized by one-electron oxidation of the triphenylene-based starting compound to form a radical cation which abstracted a chlorine atom with a concomitant rearrangement to yield the hexachloroantimonate salt. The arenium ion character is apparent from the \(^{13}\text{C}\) spectrum (three signals at \(\delta^{13}\text{C}\) 212.9, 187.6, and 173.6) and from the bond distances, which are very close to those shown for ion 91. Cation 95 can be stored at room temperature for months. This exceptional stability was attributed to the annelation to the two bicyclo[2.2.2]octane units and the spiroconjugation effect of the fluorenyl moiety.267

\[ \text{Kochi and co-workers have obtained the related novel chloro-arenium cation 96. Single-crystal X-ray crystallography revealed that the Cl–C bond is relatively long (1.86 Å), and the Cl atom is bonded to the aromatic carbon from the less hindered face to minimize steric interactions with the transannular C(8)–C(9) ethano bridge. The central ring has a distorted cyclohexadienyl structure with two short bonds [C(2)–C(3) = 1.380 Å, C(5)–C(6) = 1.353 Å] and an unusually long C(1)–C(6) bond (1.517 Å) when compared to the C(1)–C(2), C(3)–C(4), and C(4)–C(5) bonds [1.460, 1.409, and 1.413 Å, respectively]. Furthermore, the ring has a quasi-envelope conformation with C(1), C(2), C(3), and C(4) being coplanar and C(5) and C(6) lying below the plane. The cation 96 may be viewed as a positive chlorine stabilized (solvated) by an aromatic ligand as in a Wheland intermediate.}

\[ \text{Lammertsma and Cerfontain performed a detailed study on the ions generated from isomeric dimethylnaphthalenes. An interesting observation is the transformation upon increasing the temperature of cation 97 through an intermediate to cations 98 and 99. The driving force is the relief of steric strain in the } \text{peri \text{position [Eq. (3.38)]}. For the} \]
same reason, polymethylnaphthalenes are protonated at the α-position, and similar rearrangements likewise lead to the product of least strain [Eq. (3.39)].

\[
\begin{align*}
\text{Anthracenium}^{253,255,271,272} \text{ and phenanthrenium ions}^{271–274} \text{ have also been well-studied. A detailed investigation of 9-alkylanthracenes showed that protonation always occurs at C(10).}^{275} \text{ An additional methyl group at C(1) or C(8) results in the C(9) protonation as well (relief of peri strain).}
\end{align*}
\]

Of other polycyclic aromatic hydrocarbons, Laali\textsuperscript{271,272} has performed extensive studies on pyrenium cations including detailed investigations on the effect of the nature and position of substituents on the site of protonation. As Hückel calculation predicts, α-protonation is most favored (100 and 101) irrespective of the position of substituents.\textsuperscript{276} Generation of benz[a]anthracenium,\textsuperscript{277} cyclopenta[a]phenanthrenium,\textsuperscript{278} and benzo[a]pyrenium cations\textsuperscript{279} in HSO\textsubscript{3}F–SO\textsubscript{2}ClF at low temperature has also been explored.

In a recent comprehensive study with respect to the substituent effects of benz[a]anthracene carocations,\textsuperscript{280} exclusive protonation at C(7) (102) and C(12) (103, bay region protonation) in the C ring was shown to occur. The relative stability of the resulting carocations, however, strongly depends on the substitution pattern. Substrates methyl-substituted in the A ring give mixtures of the two cations. Protonation of 5-, 6-, and 7-methyl- and 7-ethyl-substituted compounds, in turn, yields
exclusively the corresponding 12-protonated 103 derivatives. Interestingly, the protonation of the 12-methyl derivative favors C(7) (cation ratio = 6.7:1), but the amount of thermodynamically more stable ipso-protonated isomer increases over time and becomes the main product (1:16). 7,12-Disubstituted compounds exhibit similar behavior. Protonation in the bay region (formation of 103) is also the main reaction with compounds with a single methyl group in the D ring.

Protonation of substituted benzo[e]dihydropyrenes with HSO₃F or HSO₃F–SbF₅ (4:1) in SO₂ClF at −78°C results in the formation of dication 104a and trication 104b. However, cations by two-electron oxidation are also formed (see Section 3.4.14).

The persistent 4-methyl[6]helicenium cation 105 has been observed and characterized by Laali and Hauser. Although the parent ion could be generated under mild conditions (TfOH–SO₂ClF), it decomposed rapidly.
Warner and Winstein have obtained the stable monocation $\text{106}$ by protonating 1,6-methano[10]annulene in HSO$_3$F. Cram and Cram have been successful in protonating [2.2]-*para*-cyclophane. The initial protonated species $\text{107}$ rearranges to the *meta*-protonated species $\text{108}$ [Eq. (3.40)].

![Diagram](image)

Protonation of bismethano[14]annulene and its bridged analogs allowed to generate and characterize the corresponding $\text{109}$ and $\text{110}$ cations. Protonation always occurs at C(7).

![Diagram](image)

### 3.4.8. Ethylenearenium Ions

The classical–nonclassical ion controversy initially also included the question of the so-called “ethylenephenonium” ions.

Cram’s original studies established, based on kinetic and stereochemical evidence, the bridged ion nature of β-phenylethyl cations in solvolytic systems. Spectroscopic studies (particularly $^1$H and $^{13}$C NMR) of a series of stable long-lived ions proved the symmetrically bridged structure and at the same time showed that these ions do not contain a pentacoordinate carbocation center (thus are not “nonclassical ions”). They are spiro[2.5]octadienyl cations $\text{111}$ (spirocyclopropylbenzenium ions)—in
other words, cyclopropyl-annulated cations in which the cationic center belongs to a cyclohexadienyl cation (benzenium ion).

\[
\begin{align*}
\text{\[111\]} & \quad \text{\[111\]}
\end{align*}
\]

The nature of the spiro carbon atom is of particular importance in defining the carbocation nature of the ions. The spirocarbon atom is of particular importance in defining the carbocation nature of the ions. \(^{13}\)C NMR spectroscopic studies have clearly established the aliphatic tetrahedral nature of this carbon, thus ruling out a “nonclassical” pentacoordinate carbocation. The positive charge is delocalized into both the dienyl framework and the spirocyclopropane moiety. As theoretical calculations demonstrated,\(^{292}\) these charge delocalizations result in almost identical C—C bond lengths in the six-membered ring (1.384–1.419 Å) and long C\(_{ipso}\)–CH\(_2\) bond distances in the cyclopropane ring (1.625 Å). Recent calculations (B3LYP/6-31G* method) clearly showed\(^{293}\) that back-bonding from the phenyl cation moiety to the ethylene fragment determines the formation of the three-membered cycle, which renders the shielding of the ipso carbon similar to that for an \(sp^3\) carbon.

The formation of the ethylenebenzenium ion 111 from \(\beta\)-phenylethyl precursors [Eq. (3.41)] can be depicted as cyclialkylation of the aromatic \(\pi\)-systems and not of the C\(_{ipso}\)–C\(_{\beta}\) bond, which would give the tetracoordinate ethylenephenonium ion. Recently, protonation of benzocyclobutene under superacidic conditions\(^{294}\) has been found to be a new independent route to generate 111 [Eq. (3.41)]. Rearrangement of the \(\beta\)-phenylethyl to an \(\alpha\)-phenylethyl (styril) ion, on the other hand, takes place through a regular 1,2-hydrogen shift. Rearrangement and equilibria of ions formed from side-chain-substituted \(\beta\)-phenylethyl chlorides have also been explored.\(^{291}\)

\[
\begin{align*}
\text{\[3.41\]} & \quad \text{\[3.41\]}
\end{align*}
\]

The ethylenebenzenium ion 111 was found to undergo isomerization to yield the \(\alpha\)-phenylethyl (styril) ion with an activation energy of \(E_a = 13 \text{ kcal mol}^{-1}\).\(^{295}\) In a recent study\(^{296}\) a value of 26.7 kcal mol\(^{-1}\) was computed [B3LYP/6-311G(d,p) level] and the styril ion was found to be more stable by 13.9 kcal mol\(^{-1}\).

Olah and co-workers\(^{297,298}\) have prepared and characterized a series of 4-substituted ethylenenaphthalenium ions 112. Eberson and Winstein\(^{299}\) have reported the \(^1\)H NMR
spectrum of ethyleneanthracenium ion 113 ($R = H$). A series of 9-substituted anthracenium ions have been studied by $^{13}C$ NMR spectroscopy.

![Diagram of ions 112 and 113](image)

The benzonorbornenyl cation 114a can be considered as the spiro cation 114b. The unsubstituted 9-benzonorbornenyl cation 115 ($R = H$) has not been observed but the NMR characterization of derivatives ($R = Me, Ph, OH, MeO$) has been reported. Recently, Laube has prepared the Sb$_2$F$_{11}$ cation of the 9-methyl derivative and reported X-ray crystal structure analysis. A remarkable feature of cation 115 ($R = Me$) is the strong bending of the C(9) bridge toward the aromatic ring ($|C(9)–C(4a)\text{ and } C(9)–C(8a)|$ bond distances = 1.897 Å, bond angle between C(9) and the C(4a)–C(8a) bond = 95.7°). Computed values [B3LYP/6-311+G(d,p)] show an even stronger bending (1.981 Å and 98.6°). These values, when compared to those of the parent benzonorbornene (2.35 Å and 126°), indicate a strong interaction. Furthermore, the aromatic ring shows bond alternations [$C(5)$–$C(6)$ and $C(7)$–$C(8) = 1.358 \text{ Å, } C(6)$–$C(7) = 1.423 \text{ Å, } C(4a)$–$C(5)$ and $C(8)$–$C(8a) = 1.395 \text{ Å}$], and the ring is nonplanar with both C(4a) and C(8a) having a pyramidalization value of $\Delta = 0.077 \text{ Å}$.

![Diagram of 114a and 114b](image)

3.4.9. Propargyl and Allenylmethyl Cations (Mesomeric Vinyl Cations)

No bona fide unsubstituted vinyl cations have yet been experimentally observed under long-lived stable ion conditions. However, experimental observations in the gas phase and calculations are available. According to spectroscopic studies, of the two structures of the vinyl cation (protonated acetylene) the planar, bridged nonclassical structure 116b, with the two protons slightly tilted toward the bridging proton, is preferred over the classical (Y-shaped) ion 116a. The energy difference between the
two structures is about 5 kcal mol\(^{-1}\).\(^{311,312}\) Subsequent Coulomb-explosion imaging (CEI)\(^{313}\) and simulated CEI studies\(^{314}\) showed, however, that the structure is not planar, but the protons trans-bent with respect to the plane of the bridge moiety.

In contrast to vinyl cations, propargyl cations \(117a\) exist in mesomeric allenyl forms \(117b\), which can serve as models for vinyl cations.

Extensive work has been carried out on these propargyl cations with a wide variety of substituents.\(^{214,315–317}\) Olah et al.\(^{316}\) found that in cation \(118\) the positive charge is extensively delocalized; that is, the contribution of the \(117b\) resonance form is significant. Komatsu et al.\(^{318}\) showed that both the \(\alpha\) and \(\gamma\) carbons become more shielded in ions bearing two or three phenylethynyl groups (cation \(119\)) due to the more extended charge dispersion.

In the early 1980s, Siehl and co-workers\(^{319,320}\) prepared two allenylmethyl cations \(120\) and \(121\) using the codeposition technique developed by Saunders et al.\(^{49}\) The cations thus prepared also exhibit extensive mesomeric vinyl cation character.
In vinyl cations (Figure 3.13), as in trisubstituted carbenium ions, the positive charge is stabilized by electron donating substituents or by aryl or vinyl groups via \( \pi \)-conjugation. Further stabilization may be achieved by \( \sigma \) participation—that is, by hyperconjugation of \( \alpha \) substituents, by complexation to a metal, or by the \( \beta \)-silyl effect.

Siehl has made extensive efforts to generate a range of stabilized vinyl cations. Protonation of an alkyne bearing an aromatic \( \alpha \) substituent and a substituent of sufficient steric bulk at the \( \beta \) position can yield stable vinyl cations (122). Both the parent mesityl-vinyl cation 123 and the \( \alpha \)-(para-methoxyphenyl)-substituted cation 124 were observed when the corresponding \( \beta \)-Si-substituted cations underwent cleavage at higher temperature (–100°C and –115°C, respectively). The cyclopropylcyclopropylenemethyl cation 125 has been prepared by the protonation of the corresponding allene [bis(cyclopropylidene)methane], and both NMR spectroscopic data and calculations (MP2/6-31G*) indicate charge delocalization due to hyperconjugation with the banana bond of the cyclopropylidene group.

Recently, Siehl and co-workers have made computational studies of the \( ^{13} \)C NMR shift of a series of \( \alpha \)-vinyl-substituted vinyl cations (1,3-dienyl-2-cations, Figure 3.14). They found that inclusion of electron correlation effects are important to get reliable data. The small differences \( (\Delta = 1–2 \text{ ppm}) \) between calculated [CCSD(T)/tzp/dz] and observed NMR chemical shifts suggest that the geometry of the cations is not significantly affected by the medium.

Siehl and, recently, Müller et al. have generated and observed a variety of \( \beta \)-silylated vinyl cations. The first successful observation by \( ^{13} \)C NMR of a persistent \( \beta \)-silyl-substituted vinyl cation was reported by Siehl et al. [Eq. (3.42)].
resonance of the cationic carbon ($\delta^{13}C$ 208.7) shows strong shielding comparable to those of vinyl cations stabilized by hyperconjugation with cyclopropyl substituents. Similar shielding effect of the $\beta$-silyl substituent was found by calculations (IGLO). Due to the hyperconjugation effect, cation 126 prefers the conformation in which the empty $2p$ orbital of the cationic carbon is parallel to the C–Si bond allowing maximal overlapping. The rotation barrier in the parent model compound about the $C^+–CH_2SiH_3$ bond was calculated to be 14.5 kcal mol$^{-1}$.

Subsequently, Siehl and Kaufmann$^{322}$ reported the synthesis and NMR spectroscopic characterization of a range of persistent $\alpha$-mesityl- and $\beta$-silyl-substituted vinyl cations (127) by protonating the corresponding alkynes at $-130^\circ$C (HSO$_3$F–SbF$_5$ in SO$_2$ClF–SO$_2$F$_2$). The $^{13}$C NMR chemical shifts values of the C$^+$ carbons show that all silyl-substituted vinyl cations shielded more strongly ($\sim$30–33 ppm) than the silicon-free analogs, which is indicative of the magnitude of the $\beta$-silyl effect.

Unusually stable vinyl cations have been prepared by Müller, Siehl, and co-workers$^{330}$ by the intramolecular addition of transient silylium ions to alkynes at room temperature. Both the $^{13}$C NMR chemical shifts for the vinyl carbons ($\delta^{13}C_\alpha = 185.8$, $\delta^{13}C_\beta = 84.1$) and the high-field shift of the ipso carbon ($\delta$ 113.7) found for 128 ($R = \text{Ph}$) are characteristic of aryl-substituted vinyl cations. The ortho and para carbon atoms are highly deshielded, which indicate that a significant amount of the positive charge is transferred to the phenyl ring. The phenyl-substituted cation was stable for weeks at room temperature, whereas the methyl-substituted analog decomposed in
several days. The difference is due to the lack of charge delocalization in the case of the latter. In contrast to the high stability of cations 128, cations 127 with only a single β-silyl substituent for hyperconjugative stabilization could only be generated in superacid media at −130°C.322

Recently, the X-ray structure of vinyl cation 129 (CB$_{11}$H$_6$Br$_5^-$ salt) has been determined.331 The disilacyclohexane ring adopts a regular chair conformation with the silicon atoms and the C$_\alpha$ and C$_\beta$ atoms nearly coplanar (Si–C$_\alpha$–C$_\beta$–Si angle = 173.9°). The molecule is linear around the vinyl bond (C$_\beta$–C$_\alpha$–C = 178.8°) with an unusually short C–C double bond (1.22 Å) indicating that the carbocation carbon is $sp$ hybridized. Furthermore, the C$_\beta$–Si bonds (1.98 and 1.95 Å) are about 0.1 Å longer than a regular C$_{sp2}$–Si bond, which can be attributed to the β-silyl hyperconjugation. Molecular structures calculated by density functional theory [B3LYP/6-31G(d)] and ab initio [MP2/6-31G(d)] method closely match the experimental solid-state geometry.

Müller et al.332 have characterized a number of α-aryl-, β,β’-disilyl-substituted vinyl cations (130). Both $^{13}$C NMR data and calculations show the effect of both $\pi$-conjugation with the aromatic moiety and σ-delocalization of the β-Si–C bonds. $\pi$-Delocalization is manifested by the marked low-field shift of the ortho and para carbon atoms compared to those of the precursor alkynes, whereas σ-delocalization is shown by the deshielding of the $^{29}$Si NMR resonance relative to the precursor silylalkyne (Δ$^2$9Si 29.5–41.4). Computed structures [B3LYP/6-31G(d) level] are all very similar, that is, calculation is not able to show the subtle interplay between σ- and $\pi$-delocalization, which is evident from the NMR spectroscopic data.

The 1-(para-methoxyphenyl)-2-(triisopropylsilyl)vinyl cation 131 has also been generated, characterized, and studied323,333 to elucidate the importance of α–π aryl and β–σ hyperconjugative stabilization. A comparison was made with the para-methoxyphenylvinyl cation 124, which has a higher demand for α-aryl π-stabilization. The para carbon of cation 131 is 7 ppm more shielded compared to that of cation 124, indicating that the β-silyl stabilization effect is operative. The experimentally determined rotation barrier of the para-methoxy substituent for 131 (<8 kcal mol$^{-1}$) and 124 (9.0 kcal mol$^{-1}$) shows a less significant double-bond character of the MeO–C(4)
bond in ion 131, that is, the existence of β-silyl effect. These findings demonstrate that σ-bond hyperconjugation contributes to charge distribution even in highly π-stabilized α-(para-methoxyphenyl)viny1 carbocations.

\]

131

To study the possible stabilizing effect of β-silyl cations, Olah and co-workers\textsuperscript{334} prepared the 2-[(1-trimethylsilyl)viny1]-2-adamantyl cation 132 [Eq. (3.43)] as well as the parent silicon-free carbocation. In contrast to the above observations, NMR data [the (C1′), (C2), and (C2′) carbons are more deshielded in 132 than in the parent ion] showed that cation 132 is destabilized compared with the silicon-free analog. Furthermore, at −100°C the C(1) and C(3) carbons were found to be equivalent, whereas in the parent ion they were nonequivalent. This indicates a rapid rotation about the C(1)–C(3) bond in 132, which can be rationalized by assuming the intermediacy of the β-silyl-stabilized cation 133. The difference between cation 132 and those having β-silyl-stabilization discussed above may be the orthogonal arrangement of the β-C–Si bond and the p-orbital of the carbocation center.

3.4.10. The Phenyl Cation

The phenyl cation (134) first postulated by Waters\textsuperscript{335} is a highly reactive species of low stability and plays a fundamental role in organic chemistry—for example, in the chemistry of diazonium ions. According to gas-phase studies and calculations, its stability is between that of the ethyl cation and the vinyl cation.\textsuperscript{336} Since it is an extremely electrophilic and short-lived species, it could not be isolated or observed directly in the condensed phase. For example, solvolytic and dediazoniation studies under superacidic conditions by Laali et al.\textsuperscript{337,338} failed to find evidence of the intermediacy of the phenyl cation. Hyperconjugative stabilization via ortho-Me\textsubscript{3}Si or ortho-tert-Bu groups, however, allowed Sonoda and co-workers\textsuperscript{339} generate and trap the corresponding substituted phenyl cations.

+ 134
Theoretical studies have shown that the singlet minimum of the parent phenyl cation lies about 20–25 kcal mol\(^{-1}\) lower than the triplet minimum. Recent \textit{ab initio} calculations have shown that electron-donating substituents in the \textit{para} position increase the relative stability of the triplet state. Benzannelation has a similar effect. Protonation of the substituents, however, dramatically increases the preference for the singlet state, with \(-\text{SH}_2^+\), \(-\text{SMeH}^+\), and \(-\text{NH}_3^+\) exhibiting the largest effect. The effect of the \(-\text{N}_2^+\) group is similar to the onium cationic substituents. Dramatic stabilization of the singlet state was also observed in \textit{ortho}-Me\(_3\)Si-phenyl cations generated by photolysis of Me\(_3\)Si-substituted chlorobenzenes. Lodder and co-workers\(^{342}\) performed photolysis of various phenyl cation precursors in the presence of anisole and correlated distinct product patterns with the singlet/triplet nature of the phenyl cations.

Winkler and Sander\(^{343}\) have recently succeeded in preparing the phenyl cation by codeposition of iodobenzene or bromobenzene with a microwave-induced argon plasma in cryogenic matrix. Cation 134 was characterized by IR spectroscopy by an intense absorption at 3110 cm\(^{-1}\). DFT studies and isotope labeling experiments show that this characteristic absorption is caused by a C–H stretching vibration involving the \textit{ortho} hydrogens. The 4-methoxyphenyl cation has recently been generated in solution by photolysis of 4-chloroanisole and detected by flash photolysis.\(^{344}\)

### 3.4.11. Arylmethyl and Alkylarylmethyl Cations

The first stable, long-lived carbocation observed was the triphenylmethyl (trityl) cation 135.\(^{6–9}\)

![Structure of the triphenylmethyl (trityl) cation 135.](image)

This ion is still the best-investigated carbocation; and its propeller-shaped structure, shown, for example, by its X-ray characterization (aromatic ring angles = 54\(^{\circ}\)),\(^{345}\) is well-recognized. Strong contribution from \textit{para}- (and \textit{ortho}-) quinonoidal resonance forms are responsible for much of the reactivity of the ion. Diphenylmethyl cations (benzhydryl cations) are considerably less stable than their tertiary analogs. Reindl et al.\(^{346}\) used force field (MMP2) and \textit{ab initio} (MP2/6-31G\(^*\)) methods to show, however, that stabilization by the phenyl group is attenuated. Thus, the resonance stabilization value of cation 135 (average value of \(-41.6\) kcal mol\(^{-1}\) for each phenyl ring) is much less than that of the benzhydryl ion 136 (\(-51.4\) kcal mol\(^{-1}\)) and the benzyl cation (\(-76.4\) kcal mol\(^{-1}\)). Although UV spectra in dilute sulfuric acid solutions have been obtained early,\(^{347}\) only in the 1960s has the benzhydryl ion 136 been observed in higher
concentrations in superacid solutions \[\text{HSO}_3\text{Cl}, \text{SbF}_5, \text{HSO}_3\text{F–SbF}_5\]. Recently, 4,4'-disubstituted benzhydryl cations have been generated by the oxidative C–H bond dissociation of the corresponding diarylmethanes. The accumulation of the cations was confirmed by $^{13}$C NMR spectroscopy: A signal for the 4,4'-difluorobenzhydryl cation was detected at $\delta^{13}$C 192.6, which is close to the value ($\delta^{13}$C 193.3) observed in superacid medium (HSO$_3$F–SbF$_5$–SO$_2$ClF).

Mono- and dialkylarylmethyl cations can be obtained readily from the corresponding alcohols, alkenes, or halides in superacid solutions, such as HSO$_3$F–SbF$_5$, HS$_2$O$_3$Cl and SbF$_5$, and oleum. Structures 137–139 are representative alkylarylmethyl cations.

Because of the high stability of the tertiary ions, these are preferentially formed in the superacid systems from both tertiary and secondary, and even primary, precursors. If, however, the tertiary carbocation is not benzylic, rearrangement to a
secondary benzylic ion can be observed\textsuperscript{350,353} (Scheme 3.5). With suitable substituent groups (which also prevent transalkylations), secondary styryl cations (140–142) were found as stable, long-lived ions\textsuperscript{291,354}

\[
\begin{align*}
140 & \quad 141 & \quad 142 \\
\end{align*}
\]

Although the unsubstituted benzyl cation is still elusive, many substituted derivatives have been observed (cations 143–146).\textsuperscript{355,356}

\[
\begin{align*}
143 & \quad 144 & \quad 145 & \quad 146 \\
\end{align*}
\]

In a cation such as the (2,4-di-\textit{tert}-butyl-6-methyl)benzyl cation 147, a high rotational barrier around the \textit{sp}\textsuperscript{2}-hybridized atom is observed. The methylene protons are found magnetically nonequivalent in the \textit{\textit{\textit{\textit{\textit{H}}}} NMR spectrum.\textsuperscript{356} Recent combined experimental and theoretical studies for the related cation 143 suggest\textsuperscript{357} that structure 143b is an important resonance contributor.

\[
\begin{align*}
147 & \quad 143 & \quad 143a & \quad 143b \\
\end{align*}
\]

No rearrangement of benzyl cations in acid solutions to tropylium ions has been found, although this rearrangement is observed in the gas phase (mass
spectrometry),\textsuperscript{358,359} and the tropylium ion was shown by \textit{ab initio} studies to lie about 7 kcal mol\textsuperscript{-1} lower in energy than the benzyl cation \textit{148a}.

Laube, Olah, and Bau have reported an X-ray crystallographic study of the cumyl cation (\textit{148c}) hexafluoroantimonate salt.\textsuperscript{360} Cation \textit{148c} is nearly planar (phenyl ring twist angle = 8°) and has a short C\textsuperscript{+}–C\textit{ipso} bond (1.41 Å), and bond distances in the phenyl ring show strong benzylic delocalization. Furthermore, a slight shortening of the C\textsuperscript{+}–Me bonds (0.025 Å) indicates weak C–H hyperconjugation. The structure and stability of a range of benzylic cations, including \textit{135}, \textit{136}, and \textit{148}, have also been calculated.\textsuperscript{346} It was found that methyl substitution at the cation center of the benzyl cation \textit{148a} increases stabilization of the carbocation carbon by C\textsuperscript{−}C\textsuperscript{0}H hyperconjugation. As a result, the C\textsuperscript{+}–C\textit{ipso} bond elongates (\textit{148a} = 1.37 Å, \textit{148b} = 1.39 Å, \textit{148c} = 1.41 Å, MP2 level). These theoretical results, in agreement with the solid-state structure and other findings discussed above, suggest that the aromaticity of the benzene ring is substantially reduced. Therefore, the best description of the benzyl cation \textit{148a} is structure \textit{148′}.

Sterically crowded arylmethyl cations have been prepared by Olah, Prakash, and co-workers.\textsuperscript{361,362} 1,1\textsuperscript{0}–Diadamantylbenzyl cations \textit{149} generated from the corresponding substituted methanols were studied to explore the extent of \textit{p}–\textit{\pi} conjugation, affected by twisting of the aromatic ring brought about by steric crowding. The Hammett plot of \textit{para}-substituted cations \textit{149} showed negligible slope. Furthermore, the \textsuperscript{13}C NMR chemical shift of the 1,1\textsuperscript{0}–diadamantylbenzyl cation (\textit{149}, R = H, \textit{\delta}\textsuperscript{13}C 286.5) was found to be much deshielded compared with the that of the dimethylbenzyl cation (\textit{\delta}\textsuperscript{13}C 255.0), and the \textit{para}-carbon chemical shifts were practically unaltered with respect to those of the parent alcohols. All these data indicate the virtual absence of \textit{\pi} resonance stabilization.
The highly crowded tris(1-naphthyl)methyl cation 150 and tris(2-naphthyl)methyl cation 151 were prepared and used to abstract hydride ion from cycloheptatriene to generate tropylium ion.\cite{363} Hydride abstraction, however, could be performed only with the less crowded cation 150.

Suzuki and co-workers\cite{364,365} studied peri-disubstituted triarylmethane–triaryl-methylium naphthalene derivatives to explore the possibility of the bridging C–H structure. In cation 152 (Ar' = Ph), the H–C\(^+\) and H–C distances were found to be 1.09 and 2.39 Å, respectively, by X-ray structure analysis. Such geometric features of the solid-state structure indicate negligible contribution from the delocalized 3c–2e bonding arrangement 152a. Consequently, these cations prefer the localized structure 152b. PM3 calculations indicated that the delocalized structure 152a is the transition state for the degenerate interconversion of 152b.

![Diagram of 152](image)

Laursen, Krebs, and co-workers synthesized a series of triangulenium cations with the general formula 153 with varied substitution patterns. These are highly stable cations with very high pK\(_R^+\) values and used as textile and laser dyes and cellular stains for diagnostic purposes. According to X-ray characterization, the geometry for trioxatriangulenium cations is planar,\cite{366,367} whereas the triazatriangulenium cations have a disc shape.\cite{368}

![Diagram of 153](image)

The same group has recently reported\cite{369} the synthesis and characterization of the [4]heterohelicenium cation 154. X-ray analysis confirmed that strong repulsion
between the methoxy substituents prevents the system being planar. Consequently, cation 154 is chiral and indeed crystallizes as a racemate. The oxygen atoms are positioned exactly above one another, and this determines a pitch of 2.7 Å of the system ([6]helicene has a pitch of 3.2–3.3 Å). Cation 154 is configurationally stable, which allowed the resolution of the racemate. The barrier for racemization was determined to be $\Delta G^\ddagger = 41.3$ kcal mol$^{-1}$ at 200°C ($t_{1/2} = 182.7$ h), which compares favorably with that of [6]helicene.

The naphthacenyl cation 155 and the indanyl cation 156 have been investigated by X-ray crystallography. The rather long C(3a)–C(7a) bond (1.456 Å) and short C(3a)–C(4) bond (1.346 Å) suggest charge delocalization into the aromatic ring.

Laali et al.$^{372,373}$ have characterized carbocations generated from substituted polycyclic aromatic compounds. The related cation 157 is a true aryl-methyl-type ion, whereas cations 158 have arenium ion character because the strongly electron-withdrawing $\alpha$-CF$_3$ group enhances charge delocalization into the pyrenyl and phenyl groups.

In a series of papers, Takekuma and co-workers$^{374–377}$ have reported the synthesis of a variety of 3-guaiazulenylmethyl cations 159 [Eq. (3.44)] with full spectroscopic characterization (UV–visible, IR, multinuclear NMR) and X-ray crystal structure analysis. The corresponding 2-furyl-, 2-thienyl-, and 2-pyrrolyl-substituted
The molecular structure of the salts reveals that the plane of the \( \text{3-guaiazulenyl group} \) is twisted from the plane of the phenyl ring (dihedral angles = 20.7–40.1°). Further data indicate that although the positive charge mainly localized on the methyl carbon, the charge is slightly transferred to the guaiazulenyl group and the phenyl group (resonance structures for the 4-dimethylamino derivative).

\end{align*}
\]

The \( \text{S}_\text{N}1 \)-type displacement reactions of chiral benzylic alcohols with aromatics catalyzed by triflic acid or HBF\(_4\)/\( \text{OEt}_2 \) have been observed by Prakash, Bach, and co-workers to exhibit high facial diastereoselectivity. This indicates the involvement of a carbocationic intermediate with a restricted conformation. Although the tert-butyl-substituted tertiary carbocation underwent \( \beta \)-elimination, they succeeded in observing the ethyl-substituted cation in \( \text{SbF}_5–\text{SO}_2\text{ClF} \) solution at \(-70^\circ\text{C}\) by NMR. The \( ^{13}\text{C} \) NMR spectrum exhibits 12 carbon signals with the most deshielded
detected at $\delta^{13}C$ 262.2 relative to acetone-$d_6$. The six carbon atoms of the aromatic rings are magnetically nonequivalent, which is due to the restricted rotation about the phenyl–C$^+$ bond. More importantly, NOE experiments showed spatial proximity of ortho hydrogens with the methyl group and the hydrogen of the stereogenic center, respectively. Such conformational restriction accounts for the observed facial discrimination.

3.4.12. Carbodications and Polycations

Interest in carbocations has not been confined to monopositive carbon species (carbomonocations). The study of carbodications has more recently been of substantial interest and the topic has been recently reviewed.\textsuperscript{379,380}

Early reports\textsuperscript{381} that a carbodication had been observed from pentamethyltrichloromethyl-benzene turned out to be incorrect. The species obtained was the dichloropentamethylbenzyl cation \textit{162}.\textsuperscript{382–384} Ionization of the 2,6-bis(chloromethyl)mesitylene, in turn, did yield the remarkably stable, unique 2,6-dimethylmesitylene-2,6-diyl dication \textit{163}.\textsuperscript{357,385} Based on the NMR data, the diallylic cation \textit{163b} appears to be the major resonance contributor to the structure, and this highly stabilized dienyl–allyl dication nature ensures the high stability. The structure is similar to that of the experimentally still elusive bisallylic benzene dication \textit{164}, although polycyclic analogs were obtained (see Section 3.4.14). Calculations (MINDO/3) by Dewar and Holloway showed\textsuperscript{386} that the benzene dication \textit{164} favors a $C_{2h}$ chair conformation, whereas Schleyer and co-workers\textsuperscript{387} found (HF/3-21G) an elongated cyclic double-allyl $D_{2h}$ geometry. The allyl units are uncoupled, thereby keeping apart the two pairs of $\pi$-electrons and minimizing mutual repulsions. The resulting unequal bond lengths force the ring out of planarity. A subsequent study by Krogh-Jespersen (HF/6-31G*$//6-31G*$)\textsuperscript{388} favored again the $C_{2h}$ chair conformation.
If two carbocation centers are separated by a phenyl ring, a variety of carbodications and carbotrications can be obtained (ions 165–167). \(^{389–391}\)

Separation of two carbocation centers by at least two methylene groups in open-chain carbodications renders them stable and observable. \(^{387,392}\) Indeed, such stable carbodications 168 have been subjected to a comprehensive NMR spectroscopic study. \(^{391}\)

Carbodications have also been observed in more rigid systems such as the apical, apical congressane (dimantane) dication 169 \(^{182}\) and the polycyclic bridgehead dication 170. \(^{182}\) The bicyclo[2.2.2]octane-1,4-diyl dication 171 was claimed to have been prepared in an earlier study. \(^{393}\) In a subsequent reinvestigation, \(^{394}\) however, dication 171 could not be detected. Instead, only the monocation monodonor–acceptor complex was obtained.

On the other hand, the bicyclo[3.3.3]undecane-1,5-diyl dication 172 (manxyl dication) was observed first by Olah et al. \(^{189}\) (the \(^{13}\)C NMR spectrum is shown in Figure 3.15) [Eq. (3.45)]. Until the generation of the 1,16-dodecahedryl dication
(see Section 3.4.3), dication $172$ was the most deshielded species observed ($\delta^{13}C$ 346.2) (Figure 3.15). Subsequently, it was also investigated by Taeschler and Sorensen$^{395}$ and was found to rearrange to dication $173$, which was independently prepared from a mixture of two isomeric dienes.

Sorensen and co-workers$^{396}$ prepared and characterized dication $174$ in an attempt to transform it into a $\mu$-hydrido bridged monocation (see Section 3.5.2.6) (Scheme 3.6). The two lowest-field $^1H$ NMR signals ($\delta$ 4.76 and 4.60) were assigned to the bridgehead protons. $^{13}C$ NMR characterization showed a $C_s$ symmetry and fluxional behavior due to a ring flip. The computed distance of the cationic centers (2.81 Å, close to the sum of the van der Waals radii) is practically identical to that found for the manxyl dication $172$ (2.80 Å). Hydride transfer to dication $174$ did not result in the formation of the desired bridged species; instead, the H–out monocation $175$ was formed, which rearranged to cation $176$.

When the dodecahedryl cation $59$ prepared by ionization of dodecahedryl derivatives or the parent hydrocarbon was left standing in the superacid medium for 6–7 h at $-50^\circ C$, it slowly and irreversibly transformed into dodecahedrane-1,16-diyldication $177$ [Eq. (3.46)]. Dication $177$ is of $D_{3d}$ symmetry and characterized by three NMR absorption ($\delta^{13}C$ 379.2, 78.8, 59.8). The $^{13}C$ chemical shifts of the positively charged centers in cation $59$ ($\delta^{13}C$ 363.9) and dication $177$ ($\delta^{13}C$ 379.2) are the most deshielded ever observed. According to calculations (SCF-MO),$^{194}$ the dodecahedrane skeleton is incapable of accommodating a planar carbocation.

---

**Figure 3.15.** The 25-MHz $^{13}C$ NMR spectrum of the bicyclo[3.3.0]undecane-1,5-diyldication $172$ in SbF$_5$–SO$_2$ClF solution. (a) Proton decoupled, (b) proton coupled.
geometry. Consequently, dodecahedryl cation 59 and dodecahedrane-1,16-diyl dication 177 can be considered true $sp^3$-hybridized carbocations.

Attempts to observe circumambulatory rearrangement in the 2,6-anti-tricyclo [5.1.0.0$^{3,5}$]octane-2,6-diyl dication 178 have been unsuccessful. The dication 178 would appear to rearrange instantaneously to the homotropylium ion 179 by proton elimination. However, substituted dications of type 178 (e.g., 180) are quite stable; they are static, and a substantial part of the charge is delocalized into the cyclopropane rings.

Several 2,6-disubstituted adamantane-2,6-diyl dications 181 have been prepared and characterized. They are stable only when they contain charge delocalizing substituents such as cyclopropyl or phenyl groups. Recently, a DFT
study (B3LYP/6-31G** level) of the adamantanediyli dication $C_{10}H_{14}^{2+}$ has been
reported.\textsuperscript{399} Interestingly, the adamantane-1,2-diyl dication $\text{182}$ is not an energy
minimum structure on the potential energy surface, whereas the adamantane-1,3-
diyli dication with two bridgehead tertiary cationic centers (\text{183}) was found to be
the most stable, being more stable by 14.6 kcal mol$^{-1}$ than \text{182}. Furthermore,
despite charge separation in structure \text{184}, this cation is less stable, although only
by 0.4 kcal mol$^{-1}$, than structure \text{183}.

\begin{center}
\begin{tabular}{ccc}
$\text{181}$ & $\text{182}$ & $\text{183}$ & $\text{184}$
\end{tabular}
\end{center}

$R = $ cyclopropyl, Ph

Additional di- and tetracations employing the adamantane skeleton were prepared
and characterized by Olah, Prakash, and co-workers. The 1,5-distonic dications \text{185}
are stabilized by both the $\alpha,\alpha$-disubstitution and bridgehead hyperconjugation.\textsuperscript{400}
Interestingly, however, the dication with cyclopropyl groups was unstable. In the
exceptionally rare, tetrahedrally arrayed tetracation \text{186} the bridgehead carbons
and the formal cationic sites are shielded, whereas carbons of the phenyl rings are more
deshielded relative to \text{185}. This indicates that in order to offset the additional charge–
charge repulsion in \text{186} relative to \text{185}, increased delocalization of the positive charge
into the phenyl groups is effected.

$X, Y = 4-$Me$_2$N, 4-MeO

$X-Y = 2-O-2'$

$Z = BF_4$, SbCl$_6$
By ionizing the respective alkenediol, Olah and co-workers\textsuperscript{403} were able to prepare the (hexaphenylttrimethylene)methane dication \textbf{188} [Eq. (3.47)].\textsuperscript{403} The dication possesses $C_3$ symmetry and adopts a propeller-like structure, but no evidence for "Y-aromatic" stabilization was found. Furthermore, the phenyl groups themselves are twisted, which prevents the optimum overlap between the $\pi$-system and the vacant $p$-orbitals at the three C(2) carbon atoms. Calculated charge density distributions and the $^{13}$C NMR data show that C(1) is not significantly deshielded for an $sp^2$ atom, indicating that the three C(2) carbon atoms and their phenyl substituents bear the charge of dication \textbf{188} similar to the trityl cation \textbf{135}.

![Chemical structure of \textbf{188} and reaction scheme](image)

Tetracation \textbf{189} and hexacation \textbf{190} have been obtained by ionizing the corresponding tetrahydroxy and hexahydroxy precursors, respectively, with triflic acid or tetrafluoroboric acid.\textsuperscript{404} These robust polytrityl cations are stable at room temperature for prolonged periods. Owing to their highly symmetric structure, the $^1H$ NMR spectra of the polycations are simple and similar to the parent trityl cation. Likewise, the $^{13}$C NMR spectra reveal a single resonance for the cationic carbons at $\delta^{13}C$ 208.15 (\textbf{189}) and 208.22 (\textbf{190}) ($\delta^{13}C$ 209.73 for the parent trityl cation).
On the basis of previous observations on the high stabilizing ability of the cyclopropyl group, Olah et al.\textsuperscript{391} made further successful attempts to prepare other dications with cyclopropyl groups. Dication 191 (R = Ph) shows significantly enhanced delocalization into the aromatic ring compared with the corresponding analogous monocation (diphenylcyclopropylmethyl cation) with partial stabilization by the cyclopropane ring. The $^{13}$C NMR shifts of the carbocation center of dication 191 (R = cyclopropyl)\textsuperscript{405} and 192\textsuperscript{227} show enhanced shielding as compared to that of the tricyclopropylmethyl cation 60 and 1,1-dicyclopropylethyl cation by 16 ppm and 12 ppm, respectively. This, again, indicates that these dications are significantly stabilized by charge delocalization involving the cyclopropane rings.

![Diagram](191-192)

The effect of the introduction of two electron-deficient centers into the bicyclo [2.2.1]heptyl skeleton (norbornyl framework) has been explored.\textsuperscript{406} A $^{13}$C NMR spectroscopic study of several substituted 2,5-diaryl-2,5-norbornadiyl dications 193 reveals the regular dicarbenium ion nature of the system.

![Diagram](193)

The bicyclic bisallylic dication 194 has been obtained from a variety of precursors under strong acid conditions.\textsuperscript{407–409}

![Diagram](194)

The endo-3,10-dimethyltricyclo[5.2.1.0$^{2,6}$]deca-4,8-dien-3,10-diyl dication 195 has been prepared\textsuperscript{410} in HSO$_3$F–SbF$_5$–SO$_2$ClF at $\sim$120°C. It possesses a novel
bishomoaromatic/allylic dication structure. At higher temperatures, 195 rearranges stereospecifically to the symmetrical cis-anti-cis-3,10-dimethyltricyclo[5.3.0.0^2,6]deca-4,8-dien-3,10-diyl dication 196 [Eq. (3.48)].

![Diagram](image)

Lammertsma and Cerfontain\textsuperscript{411} have obtained the cyclopropyldicarbinyl dication 197 by diprotonating the 1,6-methano[10]annulene in much stronger Magic Acid at $-60^\circ$C [Eq. (3.49)]. If the same protonation was carried out at $-120^\circ$C, they were able to obtain the previously discussed monocation 106.\textsuperscript{284}

![Diagram](image)

Lammertsma\textsuperscript{412} has also obtained dication 198 by the protonation of hexahydropyrene in Magic Acid solution. This is the first example of a \(\beta,\beta\)-diprotonated naphthalene derivative. Koptyug and co-workers\textsuperscript{270,413} have studied \(\alpha,\alpha\)-diprotonated hexa- and octamethylnaphthalenes 199 under superacidic conditions.

![Diagram](image)

Many aromatic stabilized dications have been prepared and characterized by NMR spectroscopy (see subsequent discussion).

Dicationic systems in which two diarylmethyl cations are linked by an 1,2-diphenylethyl,\textsuperscript{414} biphenyl,\textsuperscript{415} binaphthyl,\textsuperscript{415} or naphthalene-1,8-diy\textsuperscript{416,417} backbone have attracted great interest recently because of their unique electrochromic properties. The dications 200 were prepared from the corresponding diols\textsuperscript{416,417} [Eq. (3.50)]
and could be reversibly transformed into the acenaphthylene system. The tight geometrical constraints induce distortion of the naphthalenediyl skeleton: the $\text{C}^+\text{–C}(1)\text{–C}(8\text{a})$ and $\text{C}^+\text{–C}(8)\text{–C}(8\text{a})$ angles (125.36$^\circ$ and 126.60$^\circ$, respectively) are larger than the ideal 120$^\circ$ (data for dication $200$, $R = 4$-MeO). Each carbocation center adopts a trigonal–planar arrangement but the planes of the two centers form large dihedral angles with the plane of the naphthalene skeleton (59.7$^\circ$ and 59.6$^\circ$). This indicates that there exists only a modest conjugation between the $sp^2$ cation centers and the naphthalene backbone. This unique molecular structure results in a rather short separation of the carbenium carbons (3.076 Å), which is the shortest distance reported for such systems.

$$\text{Ar}_2\text{C} = \begin{cases} \text{Ph, 4-MeOC}_6\text{H}_4 \end{cases}$$

Oxidation of tetrasubstituted ethylenes, that is the formal removal of two electrons, yields tetrasubstituted ethylene 1,2-dications. Stable salts can be generated, however, only from tetraarylethylenes or the corresponding dihalides and diols since the aromatic rings in the resulting dication allow an efficient delocalization of the positive charge. The parent dication has been obtained by Olah et al.\textsuperscript{391} [Eq. (3.51)] and the crystal structure of the tetraanisyl dichloroiodate salt was reported.\textsuperscript{418}

$$\text{Ar}_2\text{C} = \begin{cases} \text{Ph, 4-MeOC}_6\text{H}_4 \end{cases}$$

Kochi and co-workers\textsuperscript{419} have prepared tetraanisyl dication $201$ [$R = \text{MeO}; (\text{SbCl}_6^-)(\text{Sb}_2\text{Cl}_7^-)$] by chemical oxidation, whereas electrochemical or chemical oxidation has been applied by Mori and Inoue\textsuperscript{420} to obtain chiral dications $201$ ($R = 2$-Bu, 2-octyl; $\text{SbCl}_6^-$). The X-ray crystal structure of the tetraanisyl cation ($\text{SbCl}_6^-$ salt) shows significant increases upon oxidation in both the central $\text{C–C}$ bond length and the dihedral angle about this bond from 1.359 Å and 3.8$^\circ$ of the neutral precursor to 1.503 Å and 61.6$^\circ$ of the dication. Calculated values for the AM1 optimized structure [B3LYP/6-31G(d) level] of the $R,R,R,R$-tetra-2-butyl derivative are 1.503 Å and 57.5$^\circ$.$\textsuperscript{420}$ Furthermore, the geminal anisyl groups are inequivalent with one group being more coplanar than the other (19$^\circ$ versus 28$^\circ$). Bond distances of the anisyl group also change with oxidation as a result of contribution from the quinoidal
structure. Specifically, the C(1)–C(2) and C(3)–C(4) bonds become longer (1.391 versus 1.413 Å and 1.397 Å versus 1.434 Å) whereas the Cα–C(1) and C(2)–C(3) bonds become shorter (1.492 versus 1.411 Å and 1.387 versus 1.362 Å). Interestingly, however, one pair of the vicinal coplanar anisyl groups is more involved in charge delocalization than the other pair, allowing maximum delocalization of the positive charge (structure 202).

In addition to the monocations 159 discussed in Section 3.4.11, Takekuma and coworkers have isolated the bis(3-guaiazulenyl)-substituted dications 203 and reported 1H and 13C NMR spectral data. The molecular structure of the cation 203 (X = 1,2-phenylene, Y = PF6) shows that both 3-guaiazulenylmethyl substituents twisted to the same side from the benzene ring, and one of the 3-guaiazulenyl groups is planar, whereas the other is not. Furthermore, the benzene ring is slightly distorted as result of the large steric and electrostatic interactions of the substituents. NMR data of dications with heteroaromatic central unit indicate that additional resonance structures with the positive charge delocalized into the 3-guaiazulenyl and heteroaromatic rings also contribute to the structure.

The low reactivity of 9-fluorenyl derivatives was long considered to be due to the antiaromatic character of the 4n π-electron 9-fluorenyl cation 204. Later,
however, antiaromatic destabilization of the fluorenyl cation 204 was calculated to be small, and its stability was shown to be close to that of the diphenylmethyl cation 136 (benzhydryl ion). Fluorenyl cations are quite readily formed and studied in flash photolysis experiments but have not been observed under stable ion conditions. Mills et al. have recently obtained a wide range of fluorenyl dications such as the tetrabenzo[5.5]fulvalene dication 205. These were generated by oxidizing the corresponding alkenes in SbF$_5$–SO$_2$ClF solution and could be studied by low-temperature NMR spectroscopy. The fluorenyl rings are orthogonal and $\sigma$–$p$ conjugation occurs from the C–C bond of one ring to the empty $p$ orbital of the other. Both experimental results (NMR, magnetic susceptibility exaltation, electrochemical oxidation potentials) and calculations indicate that such dicationic systems are indeed antiaromatic. However, the antiaromaticity of dication 205 is only slightly enhanced relative to that of two fluorenyl cations.

![Diagram of fluorenyl cations and dications](image)

3.4.13. Aromatic Stabilized Cations and Dications

If a carbocation or a dication at the same time is also a Hückeloid $(4n+2)\pi$ aromatic system, resonance can result in substantial stabilization. The simplest $2\pi$ aromatic system is the Breslow’s cyclopropenium ion 206. Recently, electronic and infrared spectra of the parent ion cyclo-C$_3$H$_3^+$ (206, $R = H$) in neon matrices and the X-ray characterization of the tris(trimethylsilyl) derivative were reported. The destabilizing effect of the silyl groups was found to be significantly smaller than in vinyl cations. The ion was computed to be more stable than the parent cyclopropenium ion by 31.4 kcal mol$^{-1}$ [MP3(fc)/6-311G//6-31G* + ZPVE level]. The alkynylcyclopropenylium ions 207 have been reported recently.
The benzo analogs of 206, benzocyclopropenium ions 208, are also known. Although the 2π aromatic parent cyclobutadiene dication is still elusive, substituted analogs 209 have been prepared and characterized. Ab initio calculations predicted that, in contrast to expectations, 2π electron Hückel aromatic cyclobutadiene dications have puckered structure. Evidence came from a comparison of experimental chemical shift data of tetramethylcyclobutadiene dication (209') with those calculated by IGLO (double ξ basis set) for the puckered structure. The calculated δ13C shift values for ring carbons and methyl carbons (δ13C 209 and δ13C 18.7, respectively) are nearly identical with those determined experimentally for 209' (δ13C 209.7 and δ13C 18.8, respectively).

Dications with two cyclopropenium ion moieties are known. NMR characterization of cation 210 showed significant upfield shifts of the protons of the phenyl rings and the carbons of the cyclopropenylium ring, whereas downfield shifts was noted of most of the naphthalene ring carbons when compared with cation 211. These changes presumably reflect charge delocalization to the naphthalene π-system from the cyclopropenylium rings to reduce electrostatic repulsion between the cationic rings. This information gives strong evidence that the diphenylcyclopropenylium units in dication 210 have essentially face-to-face conformation. Furthermore, pK_{R+} data indicated that cation 210 is more destabilized than cations 211 and 212, wherein the two cationic units are spaced farther away.

Among 6π aromatic systems, tropyl ion 213 and numerous substituted derivatives have been prepared and characterized (214, 215, 216, 217). The aromatic stabilization energy of tropyl ion 213 was found to be
−15.7 kcal mol\(^{-1}\), only slightly lower than that of benzene (−16.4 kcal mol\(^{-1}\)) and significantly higher than that of the phenyl ring in benzyl cation 148a (−11.2 kcal mol\(^{-1}\)).

Crystallographic characterization\(^{460}\) of cation 215 revealed that the seven-membered ring adopts a shallow boat conformation whereas the phenyl substituents possess an average dihedral angle of 80° relative to the plane of the tropylium skeleton. Since the phenyl rings can adopt either clockwise or anticlockwise orientations, cation 215 is chiral.

Both \(^1\)H NMR and \(^{13}\)C spectra of cation 218 show upfield shifts of the tropylium ring as compared with the mono-annelated cation, indicating decreased charge density on the cationic ring.\(^{461}\) Similar cations with other fused rings have been reported recently.\(^{267,462}\) In dication 219, two 218 ion fragments are connected by a triple bond.\(^{463}\) A characteristic feature of the \(^1\)H NMR spectrum of the dication 219 compared to monocation 218 is that the signal of one of the bridgehead protons extending over the triple bond is deshielded by 0.37 ppm. The results of X-ray crystallography indicate that the tropylium rings are slightly bent into a boat conformation and the two rings are twisted by an angle of 44°.

Alkylazuelenes are protonated at C(1) or C(3) position to form the stable azulenium cations 220,\(^{464}\) which can be viewed as vinyl-substituted tropylium ions [Eq. (3.52)].
The highly reactive bridged homoazulene could be easily protonated to yield the homotropylium ion \(221\) [Eq. (3.53)].

\end{array}
\end{align*}
\]

\(220\)

A variety of 1,1-disubstituted azulenes including 1,1-spiro compounds have been synthesized and then transformed by hydride abstraction to the corresponding highly stable tropylium cations \(222\). NMR characterization of the spiro-ethylene derivatives \(222, R = R = \text{CH}_2\text{CH}_2\) and a comparison with the ethylene benzenium ion indicate less delocalization of the positive charge into the cyclopropane ring (higher field shifts of the cyclopropane carbon and methylene proton signals) and the least bond alternation in the seven-membered ring (equivalent coupling constants of the vicinal protons). These data show the significant difference of the bonding arrangement of the two systems and the total chemical shift value of 323 ppm for the unsubstituted spiro-ethylene derivative indicates a classical ion nature. The high thermodynamic stability of these ions is attributed to stabilization by the inductive and \(\sigma-\pi\) conjugation of the 1,1-substituents and the \(\pi-\pi\) conjugative effect of the double bond of the five-membered ring.

\[
\begin{align*}

\text{R} & \quad \text{R} \\
\text{R} & \quad \text{R} \\
\text{R} & \quad \text{R} \\
\text{Y} & \quad \text{Y}
\end{align*}
\]

\(222\)

The synthesis and characterization of a series of azulenyl-substituted cations \(223\) showed that these are extremely stable ions, which is attributed to the dipolar structure of the azulene rings.
The β-triethylsilyl methyl tropylium ion 224 was prepared as shown in Eq. (3.54). 470 The $^{13}$C and $^{29}$Si NMR spectral features demonstrate that the β-Si substituent interacts strongly with the π-system of the tropylium ion by hyperconjugation. The $^{29}$Si NMR spectrum has a single resonance at δ$^{29}$Si 17.3 significantly deshielded from the precursor (δ$^{29}$Si 6.6) indicative of some dispersal of the positive charge to the silicon. The X-ray structure showed that the C(8)–Si bond is orthogonal to the tropylium ring thereby maximizing hyperconjugation. As a result, the C(8)–Si bond is lengthened (1.929 Å) compared with the average Si–CH$_2$(Et) (1.867 Å) and the short C(1)–C(8) (1.479 Å) bonds. Since the C–C bond distances alternate significantly, contribution of the resonance form was suggested.

Cyclooctatetraene dications 225$^{407–409}$ and benzocyclobutadiene dications 226$^{471,472}$ are well studied. The parent cyclooctatetraene dication is still elusive, despite repeated attempts to prepare it under a variety of superacid conditions.

The 10π dibenzocyclobutadiene dication 227 was prepared$^{472}$ by the two-electron oxidation of biphenylenes in excess of SbF$_5$–SO$_2$CIF solutions at $-10^\circ$C, and the octamethyl derivative 228 was also generated under similar conditions.$^{473}$
Since protonation of cyclooctatetraene is known to yield the homotropylium ion (see Section 3.5.3.1), Schröder and co-workers reasoned that the homo[15]annulenyl cation \( 229 \) can be formed by the protonation of the [16]annulene (Scheme 3.7).

Instead, the [16]annulenediyli dication \( 230 \) was obtained along with polymeric products in HSO\(_3\)F–SO\(_2\)Cl–CD\(_2\)Cl\(_2\) media at \(-80^\circ\)C. The \(^1\)H and \(^{13}\)C NMR data are consistent with the formation of the 14\(\pi\) dication \( 230 \); however, attempts to trap the dication with NaOAc–CH\(_3\)OH gave only polymeric products. Two possible mechanisms for the formation of dipositive ion \( 230 \) have been considered. The first involves initial protonation to the homo[15]annulenyl cation \( 229 \) which further undergoes protolytic cleavage to the dication \( 230 \) (by loss of a molecule of hydrogen). The second route is associated with the stepwise oxidation of annulene by the proton or the conjugate acid of sulfur dioxide (O=S=O\(^+\)), where the radical cation \( 231 \) is involved as an intermediate. Schröder and co-workers seem to prefer the second mechanisms since no hydrogen gas has been detected in the reaction.

The aromatic nature of the presently discussed carbocations and dications have been further established by subjecting their NMR parameters to charge density chemical shift relationship originally developed by Spiesecke and Schneider. Furthermore, NICS (nucleus-independent chemical shift) developed by Schleyer et al. offers a simple and efficient probe for aromaticity.

### 3.4.14. Polycyclic Arene Dications

The ease of oxidation of polycyclic aromatic hydrocarbons in the gas phase as well as in solution is well-documented. In strong acid solutions, monopositive radical ions and/or dipositive ions, also known as oxidation dications, have been reported. Similar species have been observed in anodic oxidations of
aromatic compounds in low nucleophilicity solvents. Simple Hückel molecular orbital theory predicts that arenes whose highest occupied molecular orbitals (HOMOs) are at higher energy levels (smaller $E_{\text{HOMO}}$ values) should be prone to two-electron oxidation to dipositive ions. On the other hand, the arenes with low-lying HOMOs should be more difficult to ionize. Certain polycyclic arenes have also been protonated to the corresponding dipositive ions.

Although benzene does not undergo two-electron oxidation reactions upon treatment with SbF$_5$–SO$_2$ClF, but gives instead the benzenium ion $88$ by protonation (due to HF impurity in the system), naphthalene has been reported to give the corresponding radical monocation upon treatment with SbF$_5$–SO$_2$ClF at $-78^\circ$C. However, the presence of methyl substituents on the ring lowers the ionization potential to a point that stable carbodications can be formed. Thus, the tetramethyl- and octamethylnaphthalene dications $232$ and $233$ have been prepared from the corresponding arenes.

\[
\begin{align*}
\text{CH}_3 & \quad \text{CH}_3 \\
\text{H}_3\text{C} & \quad \text{CH}_3 \\
\text{CH}_3 & \quad \text{CH}_3 \\
\text{CH}_3 & \quad \text{CH}_3
\end{align*}
\]

Anthracene and substituted anthracenes are readily oxidized in SbF$_5$–SO$_2$ClF to the corresponding carbodications $234$. They have been a subject of a $^{13}$C NMR spectroscopic study. Also, a variety of carbodications of higher homologous polycyclic arenes have been generated in SbF$_5$–SO$_2$ClF and studied by $^{13}$C NMR spectroscopy by Forsyth and Olah.

\[
\begin{align*}

\text{R, R}^2 & = \text{CH}_3 \\
\text{R, R}^1 & = \text{Br} \\
\text{R, R}^2 & = \text{H} \\
\text{R, R}^1 & = \text{Cl}
\end{align*}
\]

The preparation of the 8C-6π aromatic dication $236$ of the unknown pentalene $235$ has proven to be unusually difficult. However, the dibenzoannulated derivatives have been prepared by Rabinowitz and co-workers.
Upon treatment of dibenzo[\textit{b,f}]pentalene or the 1,9-dimethyl dibenzo[\textit{b,f}]pentalene with SbF$_5$–SO$_2$ClF at $-78^\circ$C, the two-electron oxidation product dibenzo[\textit{b,f}]pentalene dications \textbf{237} were obtained$^{497, 498}$ [Eq. (3.55)]. The observed $^1$H and $^{13}$C NMR spectral deshieldings of \textbf{237} as compared with those of their progenitors clearly establish their dicaticionic nature.

Laali and coworkers have made experimental and computational studies on oxidation dications of a range of polycyclic aromatic compounds$^{271}$ including various benzo[\textit{a}]pyrenes,$^{279, 281, 282}$ isomeric azuleno phenalenes,$^{279}$ and benzo[\textit{a}]anthracenes.$^{499}$ As mentioned, substituted benzo[\textit{e}]dihydropyrenes gave diprotonated and triprotonated cations (see Section 3.4.7). Dication 104a was shown, however to slowly transform to oxidation dication \textbf{238a}.$^{281}$ Ethanophenantrenium–carboxonium trication \textbf{238b}, formed by two-electron oxidation and ester protonation, in turn, could only be generated in the more oxidizing superacid HSO$_3$F–SbF$_5$ (1:1).$^{282}$

3.4.15. Fullerene Cations

In contrast to highly stable and prolific fullerene anionic species, fullerene cations are rare. The first fullerene cation was prepared in 1996 by Reed and co-workers$^{500}$ by single-electron oxidation of C$_{76}$ to form radical cation C$_{76}^{-\ddagger}$ isolated in solid form as the CB$_{11}$H$_6$Br$_6^{-}$ salt [Eq. (3.56)]. The cation was identified in solution by a characteristic visible–near-infrared absorption ($\lambda_{max} = 780$ nm), FT–IR and EPR spectroscopy. C$_{60}^{-\ddagger}$ was generated in an analogous way later.$^{501}$ Reed et al.$^{501}$ also succeeded in...
generating $\text{HC}_60^+$ by protonation of $\text{C}_{60}$ with $\text{H(CB}_{11}\text{H}_6\text{Cl}_6)$ in ortho-dichlorobenzene [Eq. (3.57)] and isolating the salt in solid form. The $^{13}$C NMR spectrum of $\text{HC}_60^+$ (239) shows two singlets assigned to the unique $sp^3$-hybridized carbon ($\delta^{13}C$ 56) and the cationic carbon ($\delta^{13}C^+$ 182), respectively. Additional features indicate a structure of $C_6$ symmetry. Mueller et al. have applied the scalar coupling-driven uniform-sign cross-peak NMR method (UC2Qf COSY) to experimentally characterize $\text{HC}_60^+$. Two cross-peaks at $\delta^{13}C$ 55.4 and $\delta^{13}C^+$ 182.0 are indicative of the direct bond between the protonated $sp^3$-hybridized site and the $sp^2$ cationic site. Additional cross-peaks ($\delta^{13}C$ 55.4–148.2 and 140.0–182.0) could be assigned to neighboring $^{13}$C resonances.

$$
\begin{align*}
\text{C}_{76} + \text{Ar}_3\text{N}^{+} \text{CB}_{11}\text{H}_6\text{Cl}_6^- & \rightarrow \text{C}_{70}^{+} \text{CB}_{11}\text{H}_6\text{Br}_6^- + \text{Ar}_3\text{N} \\
\text{Ar} &= \text{2,4-dibromophenyl} \\
\text{(3.56)}
\end{align*}
$$

$$
\begin{align*}
\text{C}_{60} + \text{HCB}_{11}\text{H}_6\text{Cl}_6 & \rightarrow \text{HC}_{60}^+ \text{CB}_{11}\text{H}_6\text{Cl}_6^- \\
\text{ortho-dichlorobenzene} & \text{(3.57)}
\end{align*}
$$

Subsequently, Kitagawa and Takeuchi$^{503,504}$ generated and characterized substituted fullerene cations by treating substituted fullerols with triflic acid$^{503,505}$ [Eq. (3.58)]. The resulting cations, which are stable in triflic acid for weeks, give signals for the cationic centers at $\delta^{13}C^+$ 185.6 ($R$ = Me), 180.3 ($R$ = CH$_2$Cl), 175.6 ($R$ = CHCl$_2$), 171.8 ($R$ = CCl$_3$), and 174.9 ($R$ = CCl$_2$CH$_2$Cl). These resonances are at higher fields when compared to those of aryl-substituted carbocations such as Ph$_3$C$^+$ ($\delta^{13}C^+$ 221.6) and 9-phenylfluorenyl ($\delta^{13}C^+$ 224.2), which is an indication of charge delocalization into the C$_{60}$ cage. An additional factor is an interaction between the lone pair of chlorine and the cationic center (240), which is manifested by the high-field shift of the carbon resonance with increasing number of chlorine atoms attached to the $\alpha$ carbon.

$$

\end{align*}
$$

Birkett and co-workers$^{506}$ have applied a different approach using chloride abstraction with AlCl$_3$ from Ar$_3$C$_{60}$Cl to generate pentaarylated fullerene cations.
[Eq. (3.59)]. $^1$H and $^{13}$C NMR data are consistent with cation 242 with the cationic center observed at $\delta^{13}$C$^+$ 173.74 (Ar = Ph) and $\delta^{13}$C$^+$ 171.66 (Ar = 4-FC$_6$H$_4$). This is accounted for by the transformation of the initially formed antiaromatic cyclopentadienyl cation 241 through 1,2-aryl migration.

Another method developed by Kitagawa and co-workers uses the more easily accessible fullerenes RC$_{60}$H and dimer RC$_{60}$–C$_{60}$R [R = CH$_2$P(O)(OEt)$_2$] as precursors. Treatment of RC$_{60}$–H in H$_2$SO$_4$–CF$_3$SO$_3$H (1:4) results in the formation of a solution with resonances at $\delta^{13}$C 53.66 and $\delta^{13}$C$^+$ 174.67 for the substituted $sp^3$ and the $sp^2$ cationic sites, respectively. Since the rate of cation formation depends not on acidity but on the oxidizing ability of the acids used (H$_2$SO$_4$, FSO$_3$H, CF$_3$SO$_3$H), cation formation was postulated to occur via two one-electron oxidation steps. The signal of $sp^2$ cationic site appeared as a doublet indicating the coordination of the substituent to the cationic center. Furthermore, some positive charge on phosphorus can be deduced from the $^{31}$P NMR resonance at $\delta^{31}$P 31.08, which is downfield by 7 ppm from that of the parent compound. DFT calculations found dicationic structure [(EtO)$_2$(OH)P$^+$–C$_{60}^+$] 243 to be the most stable. Further support comes from GIAO calculations, which reproduced the experimental chemical shift value quite accurately ($\delta^{13}$C$^+$ 174.60).

Kitagawa et al. used the corresponding fullerol to generate cation Cl$_2$CHC$_{70}$+(244) in CF$_3$SO$_3$H. The characteristic $^{13}$C NMR experimental resonances (in ppm) together with the GIAO calculated values (in parentheses) are shown in formula 245. Sixty-two peaks in the $^{13}$C NMR spectrum assigned to $sp^2$-hybridized carbon atoms indicate $C_1$ symmetry. This symmetry and energies for five isomeric cations calculated by the DFT method support the structure to be cation 244.
3.4.16. Heteroatom-Stabilized Cations

In contrast to hydrocarbon cations, heteroatom-substituted carbocations are strongly stabilized by electron donation from the unshared electron pairs of the heteroatoms adjacent to the carbocation center (246).\[17,509\]

\[
\begin{align*}
R_2^+ \text{C} \rightarrow X & \leftrightarrow \text{R}_2^+ \text{C} = \text{X} \\
X & = \text{F, Cl, Br, I, OR, SR, NR}_2, \text{ etc.}
\end{align*}
\]

The stabilizing effect is enhanced when two, or even three, electron-donating heteroatoms coordinate with the electron-deficient carbon atom (Scheme 3.8).

![Scheme 3.8](image)

Carbocations with \(\alpha\)-heteroatom substituents such as trimethylsilyl and nitro groups that lack a stabilizing lone pair of electrons have also been prepared and studied.\[375,510\]

3.4.16.1. Halogen as Heteroatom. In 1966 Olah, Cupas, and Comisarow\[511\] reported the first \(\alpha\)-fluoromethyl cation. Since then, a large variety of fluorine-substituted carbocations have been prepared. \(\alpha\)-Fluorine has a particular ability to stabilize carbocations via back-donation of its unshared electron pairs into the vacant \(p\) orbital of the carbocationic carbon atom. \(19^F\) NMR spectroscopy is a particularly efficient tool for the structural investigations of these ions.\[512,513\] The 2-fluoro-2-propyl cation 247 (NMR spectra, Figure 3.16) and 1-phenylfluorooethyl cation 248 are representative examples of the many reported similar ions.\[514\]

Christe et al.\[515\] have reported the first crystal structures of fluoro-substituted carbocations 247 and 249. The \(\text{C}_2\text{CF}\) skeleton of cation 247 (\(\text{AsF}_6^-\) salt) is planar and the \(\text{C}^+\)–F bond is significantly shorter than the length of \(\text{C}_{\text{sp}^3}\)–F bonds (1.285 versus 1.333 Å). The average C–C bond distance is also considerably shorter than the average length of \(\text{C}_{\text{sp}^3}\)–\(\text{C}_{\text{sp}^2}\) bonds (1.432 versus 1.510 Å). These structural characteristics indicate substantial electron back-donation from fluorine to the carbenium center and a significant methyl hyperconjugation. Bond distances in cation 249, isolated in the form of \(\text{AsF}_6^-\) and \(\text{As}_2\text{F}_{11}^-\) salts, show varied changes. Whereas the \(\text{C}^+\)–\(\text{C}_{\text{ipso}}\) bond is short, similar to those found in the trityl cation and the related cation 250,\[516\] the \(\text{C}^+–\text{F}\) bond shortens only slightly (1.31 versus 1.333 Å). The observed \(19^F\) chemical shift (\(\delta^{19}F\) 18)...
is in good agreement with that reported for Ph₂CF⁺ earlier (δ¹⁹F 11.5).⁵¹¹ A comparison of C⁺–F bond length of cation 249 with C–X bond distances of cation 250⁵¹⁶ and CH₃CX=CH₂ haloalkenes demonstrates that chlorine is a better electron back-donor than fluorine. In both cation 247 and cation 249, the carbocation carbon centers form along their 2pz axes two fluorine bridges with two different anions.

![Figure 3.16. (a) ¹H NMR spectrum of the 2-fluoro-2-propyl cation 247 at 60 MHz, J_H-F = 25.4 Hz (b) ¹⁹F NMR spectrum of the same ion at 56.5 MHz, J_H-F = 25.4 Hz.](image)

The X-ray characterization of the SbF₆⁻ salt of cation 250 by Laube et al.⁵¹⁶ corroborates the above findings. The short C⁺–Cl distance (1.668 Å versus 1.734 Å for Csp²–Cl) indicates significant chlorine back-donation resulting in partial double bond character in agreement with experimental findings and theoretical calculations.

Trifluoromethyl-substituted⁵¹⁷ and perfluorophenyl-substituted carbocations⁵¹⁸,⁵¹⁹ have also been prepared and studied. Because of the relatively large fluorine chemical shifts, anisotropy and ring current effects play a relatively much smaller role than they
do in the case of proton shifts. Therefore, a better correlation of charge distribution with chemical shifts can be obtained. The trifluorocyclopropenium ion 251 has also been reported. The $^{19}\text{F}$ NMR spectrum exhibits a single resonance at $\delta^{19}\text{F} - 63.1$, which is deshielded by 57.8 ppm relative to the neutral perfluorocyclopentene ($\delta^{19}\text{F} - 120.9$). A review has summarized the chemistry of fluorinated allyl cations including NMR characterization and the chemistry of other perfluorinated carbocations has also been reviewed.

A series of chloromethyl cations were observed, including phenylchloromethyl cations and perchlorotriphenylmethyl ion 256. West and Kwitowski have characterized the perchloroallyl cation 257. A series of chloro- as well as bromo- and iodomethyl cations have been observed (258–260) and the general stabilizing effect of halogen attached to carbocation center has been demonstrated.

Prakash, Rasul, Olah, and co-workers have performed ab initio IGLO/GIAO-MP2 studies of a series of fluorocarbocations. For the CH$_3$CHF$^+$ cation, not observed yet under stable ion conditions, the classical open carbenium ion has been found to be the global minimum on the potential energy surface (MP2/6-31G* level). The C–C bond of the methyldifluorocarbenium ion 252, observed by Olah and Mo, is longer than that in the CF$_3$CHF$^+$ cation (1.452 versus 1.433 Å). This is due to the back-donation of two fluorine atoms and the stabilization of the ion by resonance. The $C_2$ symmetry structure is the most stable conformer for the 2-fluoro-2-propyl cation 247. The long H$_2$C–CH$_3$ bond of 1.578 Å of cation 253 was shown to be aligned parallel with the empty $p$-orbital of C$^+$ which allows maximum C–C hyperconjugation. The global minimum of cation 254 is a twisted structure of $C_2$ symmetry. The monofluorocyclopropenium ion 255 shows a longer C–C bond (1.385 Å) opposite to the fluorine-substituted carbon and a shorter C–C bond (1.367 Å) adjacent to the fluorine-substituted carbon. The short C–F bond (1.274 Å), which is shorter than those of ions 247, 253, and 254, is indicative of a substantial interaction between fluorine and the cyclopropyl ring. The structural features of the difluorocyclopropenium ion and trifluorocyclopropenium ion 251 are very similar to those of cation 255. The GIAO-MP2-calculated $^{19}\text{F}$ NMR chemical shifts of the fluorocarbenium ions studied show an overall good correlation with the experimental values.
Olah, Halpern, and co-workers\textsuperscript{530,531} were able to study these effects in detail using \textsuperscript{13}C NMR spectroscopy.

\textbf{Olah et al.\textsuperscript{532,533} studied trihalomethyl cations (\(\text{CX}_3^+\), \(X = \text{Cl, Br, I}\)) under stable ion conditions. \textsuperscript{13}C NMR chemical shift values correlate well with the decreasing order of back-donation (Cl > Br > I). Similar correlation was also found for dimethylhalocarbenium ions \textsuperscript{258}. The CF\textsubscript{3}\textsuperscript{+} fluoro analog, however, could not be observed under any conditions. This can be attributed to a combination of unfavorable thermodynamics (generation of CF\textsubscript{3}\textsuperscript{+} from CF\textsubscript{4} is endothermic by about 20 kcal mol\textsuperscript{-1}) and the lack of stable alternate starting materials and a suitably strong Lewis acid.\textsuperscript{534}

Further studies included \textit{ab initio} calculations of the protonation of trihalomethyl cations [MP2 and MP4(SDTQ) levels with 6-31G\textsuperscript{*} basis set].\textsuperscript{535} The protonated trifluoromethyl dication CF\textsubscript{3}H\textsubscript{2}\textsuperscript{+} lies 79.1 kcal mol\textsuperscript{-1} higher on the potential energy surface than the trifluoromethyl cation CF\textsubscript{3}\textsuperscript{+} and has a kinetic barrier of 17.4 kcal mol\textsuperscript{-1} for deprotonation. The charge repulsion between \(\text{C}^+\) and the protonated F atom results in the lengthening of the corresponding C–F bond by 0.177 \text\AA\ and the concomitant shortening of the other two C–F bonds by 0.032 and 0.036 \text\AA. The protonated trichloromethyl dication CCl\textsubscript{3}H\textsubscript{2}\textsuperscript{+} is only 4.0 kcal mol\textsuperscript{-1} less stable than the trichloromethyl cation CCl\textsubscript{3}\textsuperscript{+}, but it has a significantly higher kinetic barrier for deprotonation (65.5 kcal mol\textsuperscript{-1}). The changes in the C–Cl bond lengths are similar to those for the CF\textsubscript{3}H\textsubscript{2}\textsuperscript{+} dication. The structure and energetics of the protonated tribromomethyl dication CBr\textsubscript{3}H\textsubscript{2}\textsuperscript{+} and protonated triiodomethyl dication CI\textsubscript{3}H\textsubscript{2}\textsuperscript{+} are similar to the other two protonated trihalomethyl dications.

Since fluorine is the most electronegative element, it should inductively destabilize carboxations. The stability of fluoromethyl cations in the gas phase decreases in the order CFH\textsubscript{2}\textsuperscript{+} > CF\textsubscript{2}H\textsuperscript{+} > CF\textsubscript{3}\textsuperscript{+} > CH\textsubscript{3}\textsuperscript{+}. The trend in solution, however, could be different, due to solvent effects, ion pairing, and so on. Indeed, fluorine has been shown to provide stabilization for carboxations. The existence of CH\textsubscript{3}CF\textsubscript{2}\textsuperscript{+}, in contrast to the elusive ethyl cation CH\textsubscript{3}CH\textsubscript{2}\textsuperscript{+}, is a clear evidence that replacement of H atoms by F atoms provides stabilization for carboxations.\textsuperscript{524} Furthermore, it was found that in perfluorobenzyl cation C\textsubscript{6}F\textsubscript{5}CF\textsubscript{2}\textsuperscript{+} fluorine atoms in resonance positions (\textit{ortho} and \textit{para}) are more deshielded than those in \textit{meta} positions.\textsuperscript{536} This indicates carboxation stabilization by back-donation.

It has been shown in a recent theoretical study\textsuperscript{537} (\textit{ab initio} calculations at the MP2/VTZ+D+P level) that \(\pi\)-donor ability in all halogens increases with F < Cl < Br < I, which is the opposite reported by Olah et al.\textsuperscript{532,533} on the basis of NMR chemical shifts. Recently,\textsuperscript{515} this discrepancy has been clarified as being caused by the assumption that
the $\sigma$ effect from F to the heavier halogens are identical for neutral halocarbons (CH$_3$CHXCH$_3$, CH$_2$CX=CH$_2$) and carbenium ions. In fact, the carbenium carbon is highly electron-deficient and more electronegative than chlorine. Consequently, in carbenium ions, chlorine becomes both a $\pi$ donor and a $\sigma$ donor. In contrast, the more electronegative fluorine is only a $\pi$ donor and strongly withdraws electrons through the $\sigma$ effect.

Schrobilgen and co-workers$^{538,539}$ have recently prepared the trichloromethyl and tribromomethyl cations by use of the noble-gas oxidant XeOTeF$_5^+$Sb(OTeF$_5$)$_6^-$ [Eq. (3.60)]. The $^{13}$C NMR chemical shifts of cations 261-Cl ($\delta^{13}$C 237.1) and 261-Br ($\delta^{13}$C 209.7) are significantly deshielded relative to CCl$_4$ ($\delta^{13}$C 96.4) and CBr$_4$ ($\delta^{13}$C −29.7), which is consistent with the earlier studies of Olah.$^{532,533}$ The cations of $D_{3h}$ symmetry were found to be planar in the solid state (sum of $C_CX$ bond angles $= 360^\circ$) with no significant interactions between $C_C^+$ and the fluorine atoms of the anion. Cation 261-Cl is disordered in the crystal and gives a slightly wider range of bond lengths and angles than that of cation 261-Br. The $C_C^+$ bond lengths are shorter than in CCl$_4$ (1.592–1.672 Å versus 1.751 Å) and CBr$_4$ (1.783–1.851 Å versus 1.91 Å).

The geometries, natural charges, and bond orders of all four CX$_3^+$ (X = F, Cl, Br, I) cations have been calculated using HF and MP2 methods.$^{523,533,538}$

\[
\begin{align*}
\text{CX}_4^+ + \text{XeOTeF}_5^+\text{Sb(OTeF}_5\text{)}_6^- & \xrightarrow{\text{SO}_2\text{ClF}} \text{CX}_3^+\text{Sb(OTeF}_5\text{)}_6^- \\
X &= \text{Cl, Br} & X &= \text{Cl} \textbf{261-Cl} \\
& & X &= \text{Br} \textbf{261-Br}
\end{align*}
\]

Recently, the triiodomethyl cation salt CI$_3^+$Al[OC(CF$_3$)$_3$]$_4^{-}$ has been obtained by the reaction of CI$_4$ with AgAl[OC(CF$_3$)$_3$]$_4$. The $^{13}$C NMR spectrum of the cation in CH$_2$Cl$_2$ solution shows a single resonance at $\delta^{13}$C 97. The $C_I$ bond length in the solid state is significantly shorter than that of CI$_4$ (2.013 versus 2.159 Å). The salt contains isolated ions with trigonal planar geometry (sum of $I_C$ angles $= 360.0^\circ$). The I...F contacts are all longer than the sum of the van der Waals radii, which indicates that the positive charge is delocalized onto the iodine atoms.

The mixed-ligand cations CBr$_n$(OTeF$_5$)$_{3-n}^+$ ($n = 1, 2$), which contain the highly electronegative fluoro analog OTeF$_5^-$ (pentafluorooxotellurate, teflate) anion, were also characterized by $^{13}$C and $^{19}$F NMR spectroscopy.$^{538,539}$ Evidence for two fluorine-containing trihalomethyl cations has also been obtained.$^{539}$ Oxidation by XeOTeF$_5^+\text{Sb(OTeF}_5\text{)}_6^-$ of CFCl$_3$ resulted in the formation of CFCl$_2^+$ characterized by multinuclear NMR spectroscopy. The $^{13}$C and $^{19}$F are significantly deshielded ($\delta^{13}$C 214.3, $\delta^{19}$F 168.6) as compared to those in the parent compound CFCl$_3$ ($\delta^{13}$C 117.1, $\delta^{19}$F −1.1). Particularly revealing is the large increase in $^1J(^{19}$F...$^{13}$C) coupling (429 versus 335 Hz) indicative of the increased $s$ character of the $sp^2$-hybridized carbon center. The CFCl$_2^+$Sb(OTeF$_5$)$_6^-$ salt could be isolated and characterized by low-temperature Raman spectroscopy. Oxidation of CF$_2$Br$_2$ presumably leads to CF$_2$Br$^+$ as the initial product, which, however, undergoes rapid halogen exchange to yield CFBr$_2^+$. Characteristic NMR data obtained at $-80^\circ$C are similar to those of ion CFCl$_2^+$. 

---

TRIVALENT CARBOCATIONS 171
3.4.16.2. Oxygen as Heteroatom. Ions 262 discussed in this section are called unsaturated oxonium ions or carboxonium ions. This latter name reflects the hybrid nature of oxonium ion (262a)–carbenium ion (262b) resonance. Carboxonium ions are classified according to substituent R. When R is hydrogen, the ions are hydroxylated ions, or secondary or acidic carboxonium ions. Ions with R = alkyl are called tertiary or alkylcarboxonium (alkoxycarbenium) ions, or nonacidic carboxonium ions. A third group of carbenium ions with oxygen participation are the acylium ions.

\[
\begin{align*}
\text{a} & \quad \text{C} = \overline{\text{O}} - \text{R} & \quad \text{R}^1 \quad \text{C}^+ - \text{O} - \text{R}^2 & \quad \text{R} = \text{H, alkyl} \\
\end{align*}
\]

Acidic Carboxonium Ions (Hydroxylated Cations). Acidic carboxonium ions are generally obtained by protonation of carbonyl compounds. Aldehydes and ketones protonate on the carbonyl oxygen atom in superacid media at low temperatures, and the corresponding carboxonium ions can be directly observed [Eqs. (3.61) and (3.62)].

\[
\begin{align*}
\text{RCHO} & \quad \overset{\text{HSO}_3\text{F-SbF}_5\text{-SO}_2}{\longrightarrow} \quad \text{RCH}=\overline{\text{O}} \quad \text{(3.61)} \\
\text{R}_2\text{CO} & \quad \overset{\text{HSO}_3\text{F-SbF}_5\text{-SO}_2}{\longrightarrow} \quad \text{R}_2\text{C}=\overline{\text{O}} \quad \text{(3.62)}
\end{align*}
\]

Even protonated formaldehyde has been observed. Protonated acetaldehyde shows two isomeric forms, with the proton on oxygen being syn or anti to the methine proton (263).

\[
\begin{align*}
\text{CH}_3-\text{C} & \quad \overset{\text{H}}{-}\text{H} & \quad \overset{\text{H}}{-}\text{O} + \\
\text{80% syn} & \quad \text{20% anti}
\end{align*}
\]

The hydroxymethyl cation forms of protonated ketones (264) and aldehydes (265) contribute to the resonance hybrid. Based on $^{13}$C NMR studies, the degree of contribution of the hydroxymethyl cation forms can be quite accurately estimated. Similar studies have been carried out using $^{17}$O NMR spectroscopy. Recent theoretical studies (MP2/6-31G* level) for protonated acetone have supported the
conclusion that the hydroxymethyl cation resonance form is only a minor contributor to the overall structure. Similar conclusion was arrived at by low-temperature IR spectroscopy in superacid solutions (HF–SbF$_5$, HF–BF$_3$) and IR photodissociation spectroscopy of protonated acetone in the gas phase. Olah and co-workers also measured one-bond $^{13}$C–$^{13}$C coupling constants in a series of protonated benzaldehydes and acetophenones.

Diprotonation is of simple carbonyl compounds has been studied theoretically (MP2/6-31G*//HF/6-31G* level). Diprotonation is increasingly favored, going from formaldehyde to acetaldehyde to acetone, which is attributed to methyl hyperconjugation. The C–O bond length of the diprotonated species becomes increasingly longer (1.305, 1.335, and 1.359 Å), indicating increasing single-bond character.

The X-ray structure of carboxonium ions and have been determined. The main features, a substantial lengthening of the C–O bonds and a shortening of the C$_{C=O}$–C bonds, were observed upon protonation of the starting ketones.

The generation of the stable cyclopropenylcarbinyl cation under superacid conditions is an exceptional example [Eq. (3.63)]. It appears that in this case the bulky tert-butyl group prevents the usually fast rearrangement of cyclopropenylcarbinyl cations to the corresponding homocyclopropenylium ions.

Protonation of homologous oxocarbon compounds (compounds in which all carbon atoms are bonded to carbonyl or enolic oxygens or their hydrated or deprotonated
equivalents\textsuperscript{563}) have been studied by Olah and co-workers.\textsuperscript{564} They have found that protonated deltic acid (2,3-dihydroxy-2-cyclopropenone, \textsuperscript{269}) and diprotonated squaric acid (1,2-dihydroxycyclobutenedione, \textsuperscript{270}) prefer planar aromatic delocalized structures. In contrast, triprotonated croconic acid (4,5-dihydroxy-4-cyclopentene-1,2,3-trione, \textsuperscript{271}) and tetraprotonated rhodizonic acid (5,6-dihydroxy-5-cyclohexene-1,2,3,4-tetraone, \textsuperscript{272}) exhibit only carboxonium type structures.

Olah, Prakash, and co-workers\textsuperscript{565} have prepared the elusive mono-\textit{O}-protonated deltic acid \textsuperscript{269} by protolysis of di-\textit{tert}-butoxy deltate in fivefold excess of Magic Acid [Eq. (3.64)]. The \textsuperscript{1}H and \textsuperscript{13}C NMR resonances of the solution at \textit{d}_{\text{1}}\textsuperscript{1}H 7.86 and \textit{d}_{\text{13}}\textsuperscript{13}C 128.7 were assigned to cation \textsuperscript{269}. The \textsuperscript{C}_{3v} symmetry structure with C–C and C–O bond lengths of 1.389 and 1.301 Å was calculated to be the global minimum. The computed \textsuperscript{13}C NMR chemical shifts (IGLO/II/MP2/6-31G* level) of all four protonated oxocarbon cations \textsuperscript{269}–\textsuperscript{272} are in good agreement with the experimental values.

\textsuperscript{13}C NMR spectral investigations have been extended\textsuperscript{566} to the study of heteroaromatic stabilized 6π 3-dioxolium and 10π benzo-3-dioxolium ions \textsuperscript{273} and \textsuperscript{274}.

Carboxylic acids are protonated in superacid media, such as HSO\textsubscript{3}F–SbF\textsubscript{5}, HF–SbF\textsubscript{5}, or HF–BF\textsubscript{3}.\textsuperscript{541,542,567–570} The NMR spectrum of acetic acid in such media at low temperature shows two OH resonances, indicating that carbonyl protonation is favored and that hindered rotation about the resultant C–OH bond occurs\textsuperscript{547,567} [\textsuperscript{275}, Eq. (3.65)]. The predominant conformer observed is the \textit{syn,anti}, although about 5% of the \textit{syn,syn} isomer has also been seen. These isomers can be readily identified from the magnitudes of the proton vicinal coupling constants. No evidence for the \textit{anti,anti} isomer has been found in either protonated carboxylic acids, esters, or their analogs.
Esters behave in an analogous fashion, with carbonyl protonation being predominant [Eq. (3.66)]. Thus, protonated methyl formate 276 is present in HSO$_3$F–SbF$_5$–SO$_2$ solution as two isomers in a ratio of 90% to 10%.  

\[
\text{HCOOCH}_3 + \text{H}^+ \rightarrow \text{HCO}^+ + \text{CH}_3\text{O}^+ \\
\text{HCOOCH}_3 + \text{H}^+ \rightarrow 90\% \quad 10\%
\]

(3.66)

The X-ray crystal structure of protonated formic acid, acetic acid, and methyl formate has recently been determined by Minkwitz and co-workers. In agreement with NMR data discussed above, the nearly equal C–O bond lengths of protonated formic acid (1.239 and 1.255 Å), protonated acetic acid (1.251–1.291 Å for various salts), and protonated methyl formate (1.260 and 1.264 Å) show efficient delocalization of the positive charge. Minkwitz et al. have also studied protonation of oxalic acid in HF–SbF$_5$ and isolated the hexafluoroantimonate of the mono- and diprotonated acid at $-75^\circ$C and $-40^\circ$C, respectively. Structural characteristics are very similar to those of the other cations discussed.

By raising the temperature of solutions of protonated carboxylic acids and esters, unimolecular cleavage reactions are observed. These reactions can be considered within the framework of the two unimolecular reaction pathways for acid-catalyzed hydrolyses of esters, involving either alkyl–oxygen or acyl–oxygen cleavage. The advantage of studies of these reactions in superacid media, as compared with the solvolytic conditions, is that the cleavage step can be isolated and studied in detail because the cleavage products generally do not undergo any further reaction.

For example, in the case of protonated carboxylic acids in HSO$_3$F–SbF$_5$–SO$_2$ solution, a reaction analogous to the rate-determining step in the unimolecular cleavage of esters is observed leading to the acyl cation and oxonium (hydronium) ion [Eq. (3.67)].

\[
\text{RCOOH}_2 + \text{H}^+ \rightarrow \text{RCO}^+ + \text{H}_2\text{O}^+ \\
\text{RCOOH}_2 + \text{H}^+ \rightarrow \text{RCO}^+ + \text{H}_2\text{O}^+ \\
\text{RCOOH}_2 + \text{H}^+ \rightarrow \text{RCO}^+ + \text{H}_2\text{O}^+ \\
\]

(3.67)
Unimolecular cleavage in this case corresponds to the dehydration of the acid, but in the case of protonated esters the cleavage pathway depends on the nature of the alkoxy group [Eqs. (3.68)–(3.70)].

\[ \begin{align*}
R\text{CH}_{3} \xrightarrow{\text{H}^{+}, +20^\circ\text{C}} \text{R} \overset{\text{+}}{\text{c}} \xrightarrow{\text{CH}_{3}\text{OH}_{2}^{+}} R\overset{\text{+}}{\text{C} = \text{O}} + \text{CH}_{3}\text{OH}_{2}^{+} \\
\text{RCH}_{3} \xrightarrow{\text{H}^{+}, -60^\circ\text{C}} \text{RCH}_{2} \overset{\text{+}}{\text{C} = \text{O}} + \text{(CH}_{3}\text{CH}_{3}^{+}} \xrightarrow{\text{hexyl cations}} \text{RCH}_{2}\overset{\text{+}}{\text{C} = \text{O}} + \text{(CH}_{3}\text{CH}_{3}^{+}} \\
\text{RC} \overset{\text{+}}{\text{H}} \xrightarrow{\text{H}^{+}, -60^\circ\text{C}} \text{RC} \overset{\text{+}}{\text{H}} + \text{(CH}_{3}\text{C}^{+}} \xrightarrow{\text{1}} \text{RC} \overset{\text{+}}{\text{H}} + \text{(CH}_{3}\text{C}^{+}} \xrightarrow{\text{2}}
\end{align*} \]

\(\text{13}^C\) NMR spectroscopic and theoretical studies (DFT, \textit{ab initio}, and IGLO) of a series of protonated cycloalkylcarboxylic acids were performed by Prakash, Olah, and co-workers.\(^{577}\) The study showed that the carboxylic carbons are deshielded to a limited degree from those of the corresponding carboxylic acids. This indicates that the cycloalkyl groups, including the cyclopropyl group, have little effect on the \(\text{13}^C\) NMR chemical shift of the carbocationic carbons of carboxonium ions. Cycloalkyl-carboxonium ions, consequently, are primarily stabilized by delocalization involving neighboring oxygen atoms.

Protonation and diprotonation of formic acid and acetic acid have also been studied theoretically (HF and MP2/6-31G* levels).\(^{553,558}\) Both cations can be visualized as the donor–acceptor complex of \(\text{H}_2\text{O}\) and diprotonated carbon monoxide (HCOH\(^{2+}\)) and protonated acetyl cation (CH\(_3\)COH\(^{2+}\)), respectively. Both dications \(277\) and \(278\) are characterized by a long C–OH\(_2\) bond and a shorter C–OH bond, suggesting that the latter retains substantial double-bond character.

\(\text{Ab initio}\) molecular orbital theory [MP4(SDTQ)/6-31G*/MP2/6-31G* level] has been used to study the mono- and diprotonation of acetic acid and methyl acetate in superacidic media.\(^{578}\) The large energy difference between the acyl-O-protonated and alkyl-O-protonated ester rules out any equilibrium between the two species. Diprotonation of the ester gives two types of gitonic dications. Of these, \(279\) is the most stable acyl-O-diprotonated species and \(280\) is the most stable alkyl–acyl diprotonated species, being more stable by 3.5 kcal mol\(^{-1}\) than the corresponding \(E\) rotamer. Acyl-O-diprotonation (dication \(279\)) results in lengthening of the acyl O–C bond.
and shortening of the alkyl O–C bond, which is opposite to what is observed in the case of dication 280.

Cubylcarboxonium ions have been also studied by Prakash, Olah, and co-workers.579,580 The parent cation 281 prepared under superacidic conditions was stable at low temperature but decomposed to cubylacylium cation 282 as a result of further protonation and dehydration [Eq. (3.71)]. In addition to cation 281, di- and tetra-carboxonium ions and the corresponding protonated methyl esters were also observed as long-lived species stable under superacidic conditions. Experimental evidence and theoretical data indicated that the strained cubyl system effectively stabilizes the carbocationic centers through C–C bond hyperconjugation (283). On the basis of 13C data, three conformers of protonated dimethyl cubane-1,4-dicarboxylate (284–286) could be identified.

\[ \text{COOH} \xrightarrow{\text{HSO}_3^-\text{F}^-\text{SO}_2\text{Cl}^-} \text{C}^+\text{OH} \xrightarrow{-30^\circ C} \text{C}^+\text{OH} \]  

(3.71)
Olah, Prakash, and co-workers\textsuperscript{581} have studied the protonation of trifluoroacetone and methyl trifluoroacetate under superacidic conditions. Only one of the possible conformers of protonated trifluoroacetone \textsuperscript{287} and protonated methyl trifluoroacetate \textsuperscript{288} were generated. Protonation of hexafluoroacetone, in turn, was not successful. The deshielding at the carbonyl carbon (38 ppm) in \textsuperscript{287} is smaller than that observed in protonated acetone (44 ppm). According to MO calculations [MP2(fu)/6-31G* level], the C–O bond in protonated trifluoroacetone is elongated, but to a smaller degree than in protonated acetone (3.6\% versus 4.1\%). The contribution of the carbenium ion structure \textsuperscript{288b} is also greatly reduced as manifested by the higher deshielding of protonated methyl acetate (22 ppm) with respect to the parent methyl acetate as compared with the slight deshielding (14.5 ppm) for the fluorinated counterpart. These features are explained by the stronger contribution of the oxonium ion resonance form \textsuperscript{287} and \textsuperscript{288a} brought about by the strong inductive electron-withdrawing effect of the trifluoromethyl group.

Protonated lactones may be prepared by direct protonation\textsuperscript{582} or by protonating hydroxycarboxylic acids\textsuperscript{583} [Eq. (3.72)]. The resulting protonated lactones exist as two conformers similar to other protonated carbonyl compounds, and they are usually stable in excess superacids.\textsuperscript{582} A notable exception is \(\alpha\)-angelicalactone, which undergoes acyl–oxygen cleavage to form protonated acetyl propionyl dication \textsuperscript{289} (Scheme 3.9).\textsuperscript{582} Similar conclusions have been arrived at in a recent study for \(\text{C}_5\text{H}_6\text{O}_2\) isomeric unsaturated lactones using sulfuric acid, with the exception that the ring-opened product was transformed to diprotonated ketoacid \textsuperscript{290} (Scheme 3.9).\textsuperscript{584} Triflic acid, in turn, brings about polymerization under identical
conditions. Acyl–oxygen cleavage is also characteristic of protonated β-lactones to yield the corresponding acyl cations \(^{585}\) [Eq. (3.73)].

\]  \hspace{1cm} (3.73)

Carboxylic acid anhydrides cleave immediately when protonated even in \(\text{HSO}_3\text{F–SbF}_5\) solution at low temperature \((-80^\circ\text{C})\).\(^{541,569}\) Monoprotonated anhydrides \(291\), however can easily be generated reacting oxocarbenium ions (acyl cations) with carboxylic acids in \(\text{SO}_2\) solution. Rapid intramolecular proton transfer between the carbonyl groups was observed by NMR.

\end{align*}
\]  \hspace{1cm} 291

Dialkyl carbonates have been studied in \(\text{HSO}_3\text{F–SbF}_5\) solution and have been shown to be protonated on the carbonyl group giving the dialkoxhydroxymethyl cation \(292\).\(^{586}\) Di-\text{tert}-butyl carbonate cleaves immediately at \(-80^\circ\text{C}\) with alkyl–oxygen fission, giving the \text{tert}-butyl cation \(1\) and the protonated carbonic acid \(293\) [Eq. (3.74)]. The structure of the latter has been established from the \(^{13}\text{C}\) NMR spectrum of the central carbon atom, which shows a quartet, 4.5-Hz long-range C–H coupling constant, with the three equivalent hydroxyl protons.\(^{586}\) Diisopropyl and diethyl carbonate cleave at a higher temperature, also via alkyl–oxygen cleavage, with initial formation of protonated alkyl hydrogen carbonates [Eq. (3.75)]. The alkyl hydrogen carbonates are also formed by protonation of their metal salts.

Carbon dioxide also reacts under superacid conditions and protonated carbonic acid can also be obtained by dissolving inorganic carbonates and hydrogen carbonates in HSO₃F–SbF₅ at −80°C [Eq. (3.76)]. It is stable in solution to about −0°C, where it decomposes to the hydronium ion and carbon dioxide.

\[
\text{CO}_3^{2-} \text{ or HCO}_3^- \xrightarrow{\text{HSO}_3F-SbF}_5 \xrightarrow{-80^\circ C} \text{H}_3\text{CO}_3^+ + \Delta \rightarrow \text{CO}_2 + \text{H}_3\text{O}^+ \quad (3.76)
\]

Minkwitz and co-workers have recently prepared the salts of protonated carbonic acid (trihydroxycarbenium hexafluorometalates) and protonated dimethyl carbonate (dimethoxyhydroxycarbenium hexafluorometalates) [Eq. (3.77)]. The cation of C₃ symmetry in the solid state shows C–O bond lengths of 1.231 Å (AsF₆⁻ salt), which are comparable to those found in protonated formic acid (1.255 and 1.239 Å). This allows the conclusion that the positive charge is delocalized over the whole cation. Likewise, the C–O bond lengths of the CO₃ unit (SbF₆⁻ salt) do not show significant differences (1.26, 1.274, and 1.300 Å). Furthermore, the two Me–O–C–O torsional angles reveal that the methyl groups do not lie in the CO₃ plane. In the ¹H NMR spectra a singlet for the protons of the hydroxyl groups of cation is observed at δ¹H 11.55 and 11.7, whereas a singlet for the hydroxyl group of cation is detected at δ¹H 11.27–11.8. It is worth mentioning here that, in addition to these two examples, the X-ray structure of the trioxygenated carbocation C(OTeF₅)₃⁺ was also determined. In the salt [C(OTeF₅)₃][Sb(OTeF₅)₆]·3SO₂ClF, the cation has C₁ crystallographic symmetry, which is very close to the optimized C₃h gas-phase geometry. Two of the three SO₂ClF molecules have short C–O contacts (2.690 and 2.738 Å).

NMR studies and \textit{ab initio} and IGLO calculations of the mono- and diprotonation of carbonic acid have been reported by Olah, Prakash, Rasul, and co-workers. The symmetrical C₃h structure was found to be the global minimum for the mono-protonated species. On the basis of ¹H and ¹³C NMR data (single sharp peaks at δ¹H 12.05 and δ¹³C 165.4), this structure was suggested by Olah and White for the observed species in superacidic solution. The same species generated in the gas phase
by electron ionization of diethyl carbonate has recently been found by single-photon IR photodissociation spectroscopy. Structure 295 of \( C_2 \) symmetry is the lowest-energy structure of diprotonated carbonic acid, which can be considered as a donor–acceptor complex of \( \text{H}_2\text{O} \) and diprotonated \( \text{CO}_2 \). The C–OH bond length of dication 295 is between the normal C–O and C=O bond lengths indicative of the delocalization of the second positive charge into the two oxygen atoms of the C–OH moieties.

![Chemical structures](image)

It is worthwhile to point out the close similarity of protonated carbonic acid (trihydroxymethyl cation, 293) with the guanidinium ion, its triaza-analog (296). The latter has been observed in superacidic solution by NMR. Both are highly resonance-stabilized through their onium forms. The observation of protonated carbonic acid as a stable chemical entity with substantial resonance stabilization also may have implications in understanding of some of the more fundamental biological carboxylation processes. Obviously, the in vitro observation in specific, highly acidic solvent systems cannot simply be extrapolated to different environments (biological systems). However, it is possible that on the active receptor sites of enzyme systems (for example, those of the carboxic anhydrase type), local hydrogen ion concentration may be very high, as compared with the overall “biological pH.” In addition, on the receptor sites a very favorable geometric configuration may help to stabilize the active species, a factor that cannot be reproduced in model systems in vitro.

**Alkylcarboxonium (Alkoxy carbene) Cations.** The ionic structure of pyrylium salts was clearly stated by Hantzsch as early as 1922. In pyrylium salts 297, there is a contribution from carbocation structures, a fact apparent in the behavior toward strong nucleophiles leading to phenols.

![Chemical structures](image)

A recent interesting example is the chiral dication 298 obtained by treatment of the corresponding diol with \( \text{HBF}_4 \) (only one enantiomer is shown). It has a pseudo-\( C_2 \)
symmetry, and the two halves of the cation are twisted by 73° around the binaphthyl axis. The two cationic planes overlap in a face-to-face manner (the distance between the two C(9) carbons is 3.53 Å).

Resonance, similar to that in pyrylium salts, was shown\textsuperscript{594,595} to exist between oxonium ion (299a) and carbenium ion (299b) forms in alkylated ketones, esters, and lactones that were obtained via alkylation with trimethyl- or triethyloxonium tetrafluoroborates\textsuperscript{596} [Eq. (3.78)]. Ramsey and Taft\textsuperscript{597} used \textsuperscript{1}H NMR spectroscopy to investigate the nature of a series of secondary and tertiary carboxonium ions (300–302).

\begin{equation}
\text{C}_2\text{H}_5\text{O} + (\text{C}_2\text{H}_5)_2\text{O}^+\text{BF}_4^- \rightarrow \text{C}_2\text{H}_5\text{O} \rightarrow \text{C}_2\text{H}_5\text{O} \quad \text{a} \\
\text{C}_2\text{H}_5\text{O} \rightarrow \text{C}_2\text{H}_5\text{O} \quad \text{b}
\end{equation}

(3.78)

As mentioned, the stabilizing effect of heteroatoms of carbenium ions increases with the number of electron-donating heteroatoms. It follows, therefore, that the stability of carboxonium ions increases in the order monoalkoxy < dialkoxy < trialkoxy. This has been demonstrated by Taft and co-workers,\textsuperscript{598} who determined relative stabilization energies, and by Kresge, Larsen, and co-workers,\textsuperscript{599} who measured enthalpies of formation. In a recent paper, however, the validity of this stability order has been questioned\textsuperscript{600} on the basis of the rates of hydrolysis of tetraphenyl orthocarbonate and triphenyl orthoformate. The stabilizing effect of oxygen has been elucidated by Kiprof et al. through analysis of natural bond order and hydride exchange reactions.\textsuperscript{601} Enthalpies of isodesmic hydride exchange reactions between \textit{tert}-butyl cation and methoxyalkanes (calculated at the G2 level of theory)
demonstrated that the addition of methoxy substituents to a carbocation increases stability through $\pi$ interaction with the oxygen. However, the incremental stabilization decreases dramatically (Scheme 3.10).

\[
\begin{align*}
\text{Me}_3\text{C}^+ + \text{OMe} & \rightarrow \text{OMe}^+ \quad \Delta H = -25.73 \text{ kcal mol}^{-1} \\
\text{Me}_3\text{C}^+ + \text{OMe} + \text{OMe} & \rightarrow \text{OMe}^+ \quad \Delta H = -44.44 \text{ kcal mol}^{-1} \\
\text{Me}_3\text{C}^+ + \text{MeO} + \text{OMe} & \rightarrow \text{OMe}^+ \quad \Delta H = -45.36 \text{ kcal mol}^{-1}
\end{align*}
\]

Scheme 3.10

The dimethylation of methyl acetate (methylation of the 1,1-dimethoxyethyl cation) was calculated to form two isomeric gitonic dications (303), which are thermodynamically more stable than the neutral ester. They are expected to be involved in the observed methyl exchange of 1,1-dimethoxyethyl cation. Rotamer 303b is more stable than the isomeric dication 303a, by 10.0 kcal mol$^{-1}$ (MP2/6-31G*$//\text{MP2/6-31G*}+\text{ZPE}$ level).

Olah and co-workers have obtained primary carboxonium ions such as methoxymethyl and phenoxymethyl cations and their halogenated derivatives (304–307).

\[
\begin{align*}
\text{CH}_3\text{OCH}_2^+ & \leftrightarrow \text{CH}_3\text{O}^=\text{CH}_2 & \text{CH}_3\text{OCHCl}^+ & \leftrightarrow \text{CH}_3\text{O}^=\text{CHCl} \\
\text{ClCH}_2\text{OCH}_2^+ & \leftrightarrow \text{ClCH}_2\text{O}^=\text{CH}_2 & \text{C}_6\text{H}_5\text{OCH}_2^+ & \leftrightarrow \text{C}_6\text{H}_5\text{O}^=\text{CH}_2 \\
\text{CH}_3\text{OCHX} & \leftrightarrow \text{CH}_3\text{O}^=\text{CHX} & X = \text{F, Cl}
\end{align*}
\]
Olah and Bollinger also carried out a $^1$H and $^{13}$C NMR spectroscopic investigation of a series of haloalkyl carboxonium ions \(^{308}\). Ionization of $\alpha,\alpha$-difluoromethyl and $\alpha,\alpha$-dichloromethyl methyl ether in SbF$_5$–SO$_2$ solution yields isomeric methoxyfluoro- and methoxychloro-carbenium ions \(^{308}\) [Eq. (3.79)]. Of the rotamers the trans isomer is obtained in higher amounts (70 : 30 for F and 81 : 19 for Cl). The calculated structures of the isomeric methoxyfluorocarbenium ions indicate that these ions are predominantly carboxonium ions rather than carbenium ions. Interestingly, at the MP4(SDTQ)//6-31G*//MP26-31G* level of calculation, the cis isomer of the methoxyfluorocarbenium ion was found to be more stable by 3.2 kcal mol$^{-1}$.

\[
\begin{align*}
\text{CH}_3\text{OCHX}_2 & \xrightarrow{\text{SbF}_5-\text{SO}_2} \xrightarrow{40^\circ} \text{H}_3\text{C}^+\text{O} = \text{C}^+ \quad \text{CH}_3\text{OCHX}_2 & \xrightarrow{60^\circ} \xrightarrow{-60^\circ} \text{H}_3\text{C}^+\text{O} = \text{C}^+ \\
\text{X} = \text{F}, \text{Cl} & \xrightarrow{40^\circ} \text{H}_3\text{C}^+\text{O} = \text{C}^+ \\
\end{align*}
\]

\[(3.79)\]

Minkwitz et al.\(^{604}\) have prepared the hexafluorometalates of cations \(^{308}\). The reaction of $\alpha,\alpha$-dichloromethyl methyl ether in HF–Lewis acid solution at $-78^\circ$C leads to the formation of chloro cation \(^{308}\)-Cl, whereas at $-65^\circ$C fluoro derivative \(^{308}\)-F is isolated as a result of chlorine–fluorine exchange [Eq. (3.80)]. Interestingly, the chlorine atom and the methyl group are trans in the hexafluoroantimonate salt of cation \(^{308}\)-Cl, whereas the fluorine atom and the methyl group are cis in cation \(^{308}\)-F. The arrangement of the C–O–C–H atoms is nearly planar with F/Cl–C–O–C torsion angles of 2.84$^\circ$ (\(^{308}\)-F) and 179.0$^\circ$ (\(^{308}\)-Cl). The C–O bond distances (1.224 and 1.479 Å for cation \(^{308}\)-F, and 1.252 and 1.517 Å for cation \(^{308}\)-Cl) reveal dominant oxonium ion character.

\[
\begin{align*}
\text{CH}_3\text{O} = \text{CHCl} & \xrightarrow{\text{HF}-\text{SbF}_5} \text{CH}_3\text{OCHCl}_2 & \xrightarrow{\text{HF}-\text{SbF}_5} \text{CH}_3\text{O} = \text{CHF} \\
\text{M} = \text{As}, \text{Sb} & \xrightarrow{\text{HF}-\text{SbF}_5} \text{H}_2\text{C} = \text{O} & \xrightarrow{\text{HF}-\text{SbF}_5} \text{H}_2\text{C} = \text{O} - \text{CH}_2\text{OH} \\
\end{align*}
\]

\[(3.80)\]

Olah et al.\(^{603}\) have observed the formation of cation \(^{309}\) (protonated fluoromethanol) upon treatment of formaldehyde in HF–SbF$_5$ [Eq. (3.81)]. When Minkwitz et al.\(^{605}\) attempted to isolate salts of the ion, however, the hydroxymethyl(methylidene) oxonium ion \(^{310}\) was obtained [Eq. (3.81)]. Crystal structure analysis of the hexafluoroarsenate salt shows that cations and anions are connected by short H–F distances, forming a three-dimensional network. The bond lengths of the C–O–C fragment (1.226 and 1.470 Å) are longer than those in formaldehyde (1.208 Å) and dimethyl ether (1.410 Å). The C–O–C bond angle is 121.2$^\circ$.

\[
\begin{align*}
\text{H}_2\text{C} = \text{O} & \xrightarrow{\text{HF}-\text{SbF}_5} \text{H}_2\text{C} = \text{O} & \xrightarrow{\text{HF}-\text{SbF}_5} \text{M} = \text{As}, \text{Sb} \\
\end{align*}
\]

\[(3.81)\]
Alkylated carboxonium ions have also been prepared by direct electrophilic oxygenations of alkanes, alcohols, and so on, by ozone or hydrogen peroxide in superacidic media \(^6\) [Eq. (3.82)].

\[
\text{CH}_3\text{CH} + \text{H}_2\text{O}_2 \text{ or } \text{O}_3 \xrightarrow{\text{HSO}_3\text{F-}\text{SbF}_5} \left[\text{CH}_3\text{CO}^+\right] \rightarrow (\text{CH}_3)_2\text{C} = \text{OCH}_3 \quad (3.82)
\]

Smit et al. \(^6\) have isolated a series of cyclic carboxonium salts (311, 312) by acylation of cycloalkenes [Eqs. (3.83) and (3.84)].

\[
\begin{align*}
\text{RCO}^+\text{BF}_4^- & \quad \text{R} = \text{tert-Bu}, \text{Ph} \\
\text{R} & \quad = \text{Me}, \text{tert-Bu}
\end{align*}
\]

(3.83)  (3.84)

Four- and five-membered cyclic carboxonium ions have been prepared by intramolecular alkylations\(^5\) using halogen- or hydroxy-substituted carbonyl compounds\(^6\) [Eq. (3.85)], \(\gamma,\delta\)-unsaturated carbonyl derivatives,\(^6\) or substituted cyclopropanes\(^6\) [Eq. (3.86)].

\[
\begin{align*}
\text{R} \quad & \quad = \text{Me, Ph, C(O)} \\
\text{R'} & \quad = \text{H, Me, Ph, cyclopropyl}
\end{align*}
\]

Cyclic cations such as 4-oxo-1,3-dioxolane-2-ylium ion 313 and 4-oxo-1,3-dioxane-2-ylium ion 314 can be prepared in intramolecular reaction of \(\alpha\)-acetoxyacyl chlorides\(^6\) or \(\beta\)-acetoxyacyl chlorides\(^6\) with SbCl\(_5\). Meerwein's
method,\textsuperscript{618} that is, the reaction of bromoethyl esters with AgBF\textsubscript{4}, was applied to generate cations \textsuperscript{315}\textsuperscript{619,620} and dications \textsuperscript{316}.\textsuperscript{621,622}

Another method, hydride abstraction of the corresponding 1,3-dioxolanes using trityl tetrafluoroborates, could not be applied to generate dications \textsuperscript{317} and trication \textsuperscript{318}. Instead, they were prepared by the ionization of the corresponding 2-methoxyethyl benzoates in HSO\textsubscript{3}F–triflic acid.\textsuperscript{623} Interestingly, all four dications gave very similar \textsuperscript{13}C NMR chemical shifts for the carboxationic centers (\(\delta^{13}C = 182.2 – 182.7\) for the dications, and 182.9 for trication \textsuperscript{318}), which is indicative of extensive charge delocalization into the neighboring oxygens. The calculated stabilities of the meta and para isomers are very similar (B3LYP6-31G*/B3LYP6-31G*+ZPE level), whereas the ortho isomer is significantly less stable (15.0 kcal mol\(^{-1}\)), which is attributed to charge–charge repulsion and higher steric constraints.

Alkylcarboxonium ions may be synthesized easily by the dehalogenation of \(\alpha\)-haloethers. In Magic Acid, first the oxygen is protonated to oxonium ion \textsuperscript{319}, which, upon increasing temperature, decomposes to yield alkylcarboxonium ion \textsuperscript{320} \textsuperscript{[Eq. (3.87)].}\textsuperscript{624} In a similar manner, protonation of \(\alpha\)-alkoxyacetic chlorides\textsuperscript{625} or acids\textsuperscript{626} also leads to carboxonium ions. The latter approach was used to generate cyclic alkylcarboxonium ion \textsuperscript{321} \textsuperscript{[Eq. (3.88)]}.
Acetals and orthoesters can be conveniently transformed to mono- and dialkoxycarbenium ions by cleavage of an alkoxy anion [Eq. (3.89)]. The method can also be applied to transform tetraalkoxymethanes to trialkoxycarbenium ions. This method was reported early by Meerwein to generate alkoxyxycarbenium ions. Acetals can also be transformed to dialkoxycarbenium ions using hydride-abstracting agents such as trityl cations or trialkyloxonium ions.

Results with respect to the synthesis of fluorinated alkylcarboxonium cations have recently been reported. Olah, Prakash, and co-workers have methylated trifluoroacetone and methyl trifluoroacetate in CH$_3$F–SbF$_5$–SO$_2$ solution at $-60^\circ$C and observed the methylated ions as long-lived species by NMR spectroscopy. Conformers and were identified by calculation [MP2(fu)/6-31G$^*$ and MP2/6-31G$^*+ZPE$ levels, respectively]. The magnitude of the deshielding at the carbonyl carbons, again, indicates a stronger contribution of the corresponding oxonium ion resonance forms in both cases.

Stable fluorinated bis(alkoxy)methyl cations and tris(alkoxy)methyl ion were prepared reacting the corresponding difluoroformals and fluoroorthoester with excess SbF$_5$. TRIVALENT CARBOCATIONS
The X-ray structure of a number of alkoxycarbenium ions has been determined. An interesting example is 2-methoxy-1,7,7,7-tetramethylbicyclo[2.2.1]hept-2-ylidene tetrafluoroborate \( \text{326} \). It is a substituted 2-norbornyl cation and, indeed, the C(2)–C(1)–C(6) bond angle (98.8°) and the C(1)–C(6) bond distance (1.603 Å) indicate \( \sigma \)-bond charge delocalization, that is, the contribution of the \( \text{326b} \) resonance form.

Recently, a variety of \( O \)-silylated carboxonium ions have been prepared and characterized by NMR spectroscopy. Kira et al. used the Corey hydride transfer method, whereas Olah, Prakash, and co-workers applied triphenylmethyl tetrakis(pentafluorophenyl)borate to silylate esters, ketones, enones, and carbonates [Eq. (3.91)]. The ions thus produced are resonance hybrids of oxocarbenium (\( \text{327b} \)) and carboxonium (\( \text{327a} \)) ions with the latter as the major contributors. Calculated (DFT/IGLO) \( ^{29}\text{Si} \) NMR chemical shifts agree well with the experimental data.

\[
\begin{align*}
\text{R} & = \text{alkyl, aryl, MeO} \\
\text{R} & = \text{alkyl, aryl, MeO}
\end{align*}
\]

\[
\begin{align*}
\text{327a} & \quad \text{327b}
\end{align*}
\]

\( ^\text{Acylium Ions (Acyl Cations)} \). In a recent study de Rege, Gladysz, and Horváth have observed protonated carbon monoxide by IR and NMR spectroscopy at high CO pressure. Protonation occurs at the carbon to give formyl cation \( \text{328} \) [Eq. (3.92)]. A fast proton exchange observed with increasing temperature was attributed to the formation of isoformyl cation \( \text{329} \) and diprotonated CO (protoformyl dication, \( \text{COH}^2+ \)).

\[
\begin{align*}
\text{CO} & \quad \text{HF}–\text{SbF}_5 \\
25^\circ\text{C}, & \quad P_{\text{CO}} < 100 \text{ atm}
\end{align*}
\]

Protonation of carbon monoxide have been studied theoretically. Both the formyl cation \( \text{328} \) and the isoformyl cation \( \text{329} \) are protonated in exothermic processes with cation \( \text{328} \) being more stable by 38 kcal mol\(^{-1}\). The calculated energy barrier of rearrangement (36 kcal mol\(^{-1}\) at MP3/6-31G** level), however, suggests that cation \( \text{329} \), once formed, is a relatively long-lived species. Furthermore, deprotonation of diprotonated CO has significant kinetic barriers (Scheme 3.11). Calculated optimized structures (HF/6-31G* level) and energy values (in hartree) of CO, monoprotonated CO (\( \text{HCO}^+ \)), and diprotonated CO (protoformyl dication, \( \text{COH}^2+ \)), all with \( C_{\text{env}} \) symmetry, are given in Figure 3.17. According to calculations, the
protoformyl (hydroxymethine) dication is kinetically stable and has a very short C–O bond and a deprotonation barrier of $>20$ kcal mol$^{-1}$.

According to a recent $ab$ initio molecular dynamic simulation study$^{639}$ formation of formyl cation 328 is optimally favored in the 1:1 HF–SbF$_5$ solution. No evidence, however, was found for the formation of the isoformyl cation 329 and diprotonated CO. The fast proton exchange observed earlier was suggested to occur between HCO$^+$ and HF(HF)$_n$ or SbF$_6$.$^-$

Christe, Prakash, Olah, and co-workers$^{534}$ have made a comparative experimental and theoretical study of the halocarbonyl cations (XCO$^+$). ClCO$^+$, BrCO$^+$, and ICO$^+$ were observed in the condensed state in SO$_2$ClF solution by $^{13}$C NMR spectroscopy,$^{640}$ and FCO$^+$ was also reported to be generated in HSO$_3$F–SbF$_5$.$^{641}$ The new study has shown, however, that FCO$^+$ cannot be stabilized in the condensed phase with presently known Lewis acids. CICO$^+$, in turn, could be generated with Sb$_3$F$_{15}$ having sufficient acidity to form salt 330 [Eq. (3.93)]. Aubke and co-workers$^{642}$ have also reported the generation in SbF$_5$ medium and characterization by vibrational spectroscopy of the salts of CICO$^+$ with oligomeric fluoroantimonate anions.

\[
\begin{align*}
\text{F} & \quad \text{Cl} \quad \text{SbF}_5-\text{SO}_2\text{ClF} \quad -78^\circ C \\
\text{C} & \quad \equiv \quad \text{O} \\
\text{Cl} & \quad \equiv \\
\end{align*}
\]

(3.93)

In 1943, Seel observed$^{14}$ the first stable acyl cation. Acetyl fluoride with boron trifluoride gave a complex (decomposition point 20°C) that was characterized as the acetyl tetrafluoroborate salt 331 [Eq. (3.94)].

\[
\begin{align*}
\text{CH}_3\text{COF} & \quad + \quad \text{BF}_3 \\
\text{CH}_3\text{C} & \quad \equiv \quad \text{O} \\
\text{BF}_4^- & \quad \equiv \\
\end{align*}
\]

(3.94)

The identification was based on analytical data and chemical behavior. Only in the 1950s were physical methods like infrared and NMR spectroscopy applied, making further characterizations of the complex possible. Since 1954, a series of other acyl and substituted acyl cations have been isolated and identified.$^{91,643–647}$

\end{align*}
\]

Figure 3.17. Calculated optimized structures (HF/6-31G* level) and energy values (in hartree) of CO, along with monoprotonated and diprotonated CO.
The hexafluoroantimonate and hexafluoroarsenate complexes were found to be particularly stable.  

Deno et al. investigated solutions of carboxylic acids in sulfuric acid and oleum. They observed protonation at lower acid concentrations and dehydration, giving acyl cations, at higher acidities [Eq. (3.95)].

\[
\text{RCOOH} + \text{H}_2\text{SO}_4 \rightarrow \text{RCOOH}_2^+ + \text{oleum} \rightarrow \text{RCO}^+ + \text{H}_3O^+ \quad (3.95)
\]

The investigation of acyl cations in subsequent work was substantially helped by NMR. Not only \( ^1\text{H} \), but also \( ^2\text{H} \), \( ^{13}\text{C} \), \( ^{19}\text{F} \), and \( ^{17}\text{O} \) resonance studies established the structure of these ions. These investigations based on \( ^{13}\text{C} \) and proton resonance showed that acyl cations, such as the CH\(_3\)CO\(^+\), acetyl ion 331, are not simple oxonium ions (acylonium complexes), but are resonance hybrids of the oxonium ion, acyl cation, and the ketene-like nonbonded mesomeric forms. The X-ray crystallographic study of the CH\(_3\)CO\(^-\) SbF\(_6\) salt substantiated this suggestion and provided convincing evidence for the linear structure of the crystalline complex.

The experimental \( ^{13}\text{C} \) chemical shift of the carboxonium carbon at \( \delta^{13}\text{C} 150.3 \) is well-reproduced by calculation (\( \delta^{13}\text{C} 158.5 \) by the GIAO-MP2 method at the qz2p/dzp level). With respect to \( ^{17}\text{O} \) NMR results, IGLO(II) and GIAO-MP2(qz2p/dzp) calculations give a shielding of 56 ppm (\( \delta^{17}\text{O} 340.8 \)) for the acetyl cation with respect to carbon monoxide (\( \delta^{17}\text{O} 397.0 \)), which is an excellent agreement with the experimentally observed shielding of 50 ppm (\( \delta^{17}\text{O} 299.5 \)) relative to carbon monoxide (\( \delta^{17}\text{O} 350.0 \)). This reveals that the C—O bonding character of the acetyl cation is less than that of a triple bond but significantly more than that of a C—O double bond.

Investigation of acyl cations has been extended to the study of cycloaclylium ions 332–336, diacylium ions (dications) 337–339, and unsaturated acylium ions 340–342. Computational studies at various levels of theory have also been performed.  

\[
\begin{align*}
\text{332} & \quad \text{333} & \quad \text{334} & \quad \text{335} & \quad \text{336} \\
\text{337} & \quad \text{338} & \quad \text{339} & \quad \text{340} & \quad \text{341} & \quad \text{342}
\end{align*}
\]
The structure of alkenoyl cations (unsaturated acylium ions) was studied by Olah et al.\textsuperscript{658} by NMR spectroscopic methods. They found only a limited contribution from structure 343b and a substantial contribution of the delocalized ketene-like structure 343c, which is due to the ability of the $\pi$-electrons of the double bond to stabilize the positive charge. Substitution at the $\beta$-carbon increases further the importance of 343c relative to 343a. Diprotonation of propenoyl and isopentenoyl cations studied theoretically \textit{[ab initio GIAO–CCSD(T)]}\textsuperscript{659} has been shown to result in the formation of dication 344 (tertiary carbenium–acylium dication); that is, the positive charges are localized primarily on CO and the $\beta$-carbon.

\end{align*}$

Prakash, Olah, and co-workers have shown that ketenes can also be transformed to acylium ions. Both the protonation and silylation of ketenes take place exclusively at
the β-carbon to yield stable acylium ions 346 [Eq. (3.97)] and 347 [Eq. (3.98)]. A comparison of $^{13}$C NMR chemical shift data show that both C$_{\alpha}$ and C$_{\beta}$ in cation 347 are more deshielded than in cation 346 (R = Ph) ($\Delta\delta^{13}C_{\alpha} = 32.4$ ppm, $\Delta\delta^{13}C_{\beta} = 10.4$ ppm). These data indicate that cation 346 is primarily stabilized by delocalization involving oxygen (oxonium ion character), whereas β-silyl hyperconjugation results in enhanced charge delocalization in cation 347. Interestingly, DFT calculations (B3LYP/6-311+G* level) predict that O-silylation of diphenylketene is preferred over C-silylation by 5.4 kcal mol$^{-1}$, whereas for the parent ketene C-silylation is preferred by 8.2 kcal mol$^{-1}$.

3.4.16.3. **Sulfur as Heteroatom.** Thiols and sulfides are protonated on sulfur in superacid media and give mono- and dialkylsulfonium ions, respectively. Thiocarboxylic acids, S-alkyl esters, thioesters, dithioesters, and thiocarbonates in similar media also form stable protonated ions such as cations 348–353.

\end{align*}
\]

Minkwitz and co-workers have recently obtained the X-ray crystal structure of protonated thiocarboxylic acid, protonated O,S-dimethyl dithiocarbonate, and protonated dimethyl trithiocarbonate. Protonated thiocarboxylic acid 354 has C–S bond lengths of 1.683–1.708 Å. The small differences imply a nonequal distribution of the positive charge over the S atoms. All hydrogen atoms have \textit{trans} positions and they are
not located in the CS$_3$ plane, resulting in a $C_1$ symmetry. The cations have contacts with the F atoms of the anions through H bonds with bond distances smaller than the sum of the van der Waals radii.

The C–S lengths (1.692 and 1.702 Å) and the C–O bond length (1.293 Å) of the protonated $O,S$-dimethyl dithiocarbonate cation 355a are between those of typical single and double bonds. A planar $sp^2$ hybridization is indicated by the sum of 360° of the corresponding angles around the central carbon atom with the methyl groups having out-of-plane arrangements. Two cations make contact via hydrogen bonds with two anions in the solid state. Strong anion–cation interactions were also detected in the protonated dimethyl trithiocarbonate salt 355b. The central carbon is planar and has one shorter C–S(H) bond (1.722 Å) and two longer C–S(Me) bonds (1.681 and 1.682 Å). The H and the methyl substituents are slightly out of the CS$_3$ plane.

Sulfur-stabilized heteroaromatic species such as 356 and 357 are also known.

A series of thioketones have also been protonated to form carbosulfonium ions 358 and studied by $^{13}$C NMR spectroscopy. It was found that deshielding of the thiocarbonyl carbon is much less pronounced than that of ketones. This shows that there is significant mercaptocarbenium 358b contribution to the overall protonated thioketone structure. However, this is not the case in the case of protonated ketones.

Olah and coworkers have used ab initio methods (MP2/6-311+G** level) to calculate the structures of diprotonated superelectrophilic formaldehyde and thioformaldehyde dications. In both cases, the heteroatom-diprotonated structure
was found to be more stable (by 53.5 kcal mol\(^{-1}\) and 27.6 kcal mol\(^{-1}\), respectively) than the 3\(c\)–2\(e\) bonded structure 360.

Tertiary carboxonium ions may be generated using the methods applied for the synthesis of tertiary carboxonium ions. The alkylation of thiocarbonyl compounds, preferably by trialkyloxonium ions,\(^{667}\) is the most widely used procedure. Dehalogenation of \(\alpha\)-halothioethers\(^{668}\) [Eq. (3.99)] and hydride abstraction with trityl salts are also practiced\(^{669}\) [Eq. (3.100)]. Minkwitz and Meckstroth\(^{670}\) have obtained the Cl\(_2\)C=SCl\(^+\) and Cl\(_2\)C=SBr\(^+\) cations by the oxidative halogenation of thiophosgene in AsF\(_5\) solution.

The cleavage of the sulfur–carbon bond of thioacetals and thioketals,\(^{671}\) thioorthoformates\(^{672}\) [Eq. (3.101)], and tetraalkyl thioorthocarbonates\(^{673}\) [Eq. (3.102)] leads to the corresponding mono-, di-, and trithiocarbenium ions, respectively. Trimethylthiocarbenium ion 361 was also prepared by methylating dimethyl trithiocarbonate [Eq. (3.102)].

Miller et al.\(^{674}\) generated the interesting long-lived dication 362 treating hexathia-1,3,5,7-tetramethyladamantane with acids (triflic acid, fuming H\(_2\)SO\(_4\), or 25\% Magic
Acid) at room temperature. The $^{13}\text{C}$ NMR chemical shift of dication 362 ($\delta^{13}\text{C} 230$) closely matches that of the related cation 363 ($\delta^{13}\text{C} 229$).  

\[ \text{362} \quad \text{363} \]

A series of thiobenzoyl cations 364 have been prepared and studied using a metathetic silver salt reaction [Eq. (3.103)].

\[ \text{364} \quad \text{(3.103)} \]

A controversial issue of heteroatom-stabilized cations is the relative stabilization of carbocationic centers adjacent to oxygen and sulfur. In solution studies, $\alpha$-O-substituted carbocations were found to be stabilized more than $\alpha$-S-substituted carbocations. Gas-phase studies reached an opposite conclusion, whereas subsequent theoretical studies (high-level ab initio methods) supported the findings of solution chemistry. Recent results, namely, basicities of various vinylic compounds (365–370) measured in the gas phase also support this conclusion. Although mono-heteroatom-substituted compounds 365 and 366 were found to have similar proton affinities, an additional $\alpha$-methyl group increased the stability of the carbenium ion derived from 367 more than that of the sulfur counterpart 368. Even larger differences were found between proton affinities of the bis-heteroatom-substituted compounds 369 and 370.

\[ \text{365} \quad \text{366} \quad \text{367} \quad \text{368} \quad \text{369} \quad \text{370} \]

3.4.16.4. Nitrogen as Heteroatom. Amides are protonated on the carbonyl oxygen atom (cation 371) in superacid media at low temperatures, as shown first
by Gillespie and Birchall\textsuperscript{681} [Eq. (3.104)]. The same conclusion has been arrived at in a recent multinuclear NMR characterization of the cation CF\textsubscript{3}C(OH)NH\textsubscript{2}\textsuperscript{+}. \textsuperscript{682}

\[ R - C = O \xrightarrow{H^+} R - C(=O)NH\textsuperscript{+} \quad \text{(3.104)} \]

It was claimed that protonation of ethyl \(N,N\)-diisopropyl carbamate, a hindered amide, takes place on nitrogen and not on oxygen.\textsuperscript{683} A reinvestigation, however, established that at low temperature initial \(O\)-protonation takes place (kinetic control) with the \(O\)-protonated amide subsequently rearranging to the more stable \(N\)-protonated form (thermodynamic control).\textsuperscript{684} The possibility of observing the protonated amide linkage in strong acid media has particular relevance in the study of peptides and proteins.\textsuperscript{685,686} There is, however, a notable exception. Since the bridgehead nitrogen of 2,2\,-dimethyl-6-oxoquinuclidine \textsuperscript{372} is more basic than nitrogen of usual amides, and resonance stabilization of the \(O\)-protonated form is not possible, exclusive \(N\)-protonation takes place\textsuperscript{687} (\textsuperscript{373}) [Eq. (3.105)].

\[ H^+ + N\textsuperscript{+} \quad \text{(3.105)} \]

Protonation of aroyl azides and \(\alpha\)-ketonitriles in superacid media (HSO\textsubscript{3}F–SbF\textsubscript{5}, \(-78^\circ\text{C}\)) occurs exclusively on the oxygen to yield \(\alpha\)-azidocarboxonium ions \textsuperscript{374} and \(\alpha\)-cyanocarboxonium ions \textsuperscript{375},\textsuperscript{689} respectively.

The structures and \(\textsuperscript{13}C\) and \(\textsuperscript{15}N\) NMR chemical shifts of urea and its mono-, di-, and triprotonated forms have been calculated using high-level \textit{ab initio} (MP2/6-311\textsubscript{G*}) and IGLO methods.\textsuperscript{690} Protonated urea (uronium ion) is a resonance-stabilized cation. The \(O\)-protonated structure uronium ion \textsuperscript{376a} of \(C_1\) symmetry was found to be more stable by 5.8 kcal mol\textsuperscript{-1} than the \(N\)-protonated isomer \textsuperscript{376b}. The NMR spectra of urea solutions in H\textsubscript{2}SO\textsubscript{4} and HNO\textsubscript{3} (0\textdegree\text{C}), as well as NMR spectra of HSO\textsubscript{3}F–SO\textsubscript{2}ClF
(-80°C), consist of a single peak (δ\textsuperscript{13}C ~ 160, δ\textsuperscript{15}N ~ 79). The equivalence of the \textsuperscript{15}N NMR peak indicates that O- and N-protonated uronium ion forms undergo rapid exchange. Compared to chemical shifts of urea, the carbon in uronium ion is 1.5 ppm shielded and nitrogen is 3.2 ppm deshielded. These changes compare well with the IGLO calculated chemical shifts. Of the diprotonated ureas, the O,N-diprotonated form \textbf{377} of \textit{Cs} symmetry is more stable by 22.3 kcal mol\textsuperscript{-1} than the \textit{O,O}-diprotonated form. The calculated bond distances—that is, a longer C–O, a longer C–NH\textsubscript{3} and a shorter C–NH\textsubscript{2} bond compared to urea—clearly indicate that one of the positive charges is localized on N, and the other charge is delocalized among O–C–N. This was already described by Olah and White\textsuperscript{691} when obtaining the \textsuperscript{1}H and \textsuperscript{15}N NMR spectra of ion \textbf{377}. In the case of triprotonated urea, which was not observed experimentally, the preferred structure is the \textit{O,N,N}-triprotonated form \textbf{378} (X = O). This, however, is only 1.8 kcal mol\textsuperscript{-1} more stable than the \textit{O,O,N}-triprotonated form.

Similar studies have also been performed with thiourea.\textsuperscript{692} Thiourea is monoprotonated in HSO\textsubscript{3}F–SO\textsubscript{2}ClF solution, and diprotonation occurs upon addition of SbF\textsubscript{5} [Eq. (3.106)]. Monoprotonation was calculated to be exothermic by 214.2 kcal mol\textsuperscript{-1}. Further protonation of \textbf{379} to form \textbf{380}, again, is exothermic by 60.1 kcal mol\textsuperscript{-1}. The changes in bond distances upon diprotonation of thiourea show similar tendencies found for diprotonation of urea, indicating a similar charge localization/delocalized pattern. Both cations were isolated as the AsF\textsubscript{6} salts and characterized by low-temperature Raman spectroscopy (−110°C). With respect to the calculated structures (B3LYP/6-31G* level), the conclusions are very similar to those found for urea. Structure \textbf{379} of \textit{Cs} symmetry is 20.0 kcal mol\textsuperscript{-1} more stable than the N-protonated thiouronium ion. This observation is in agreement with earlier X-ray structure analysis of thiouronium nitrate.\textsuperscript{693} The \textit{S,N}-diprotonated form \textbf{380} (\textit{Cs} symmetry), the only structure observed by NMR spectroscopy, is the lowest in energy and 8.3 kcal mol\textsuperscript{-1} more stable than the \textit{S,S}-diprotonated form. The preferred structure of triprotonated thiourea, not observed experimentally, is the \textit{S,N}, N-triprotonated form \textbf{378} (X = S) being only 0.9 kcal mol\textsuperscript{-1} more preferred than
the \(S,S,N\)-triprotonated form. However, including zero-point vibrational energy makes the latter to be more stable by 1.1 kcal mol\(^{-1}\).

\[
\begin{align*}
\text{S} & \quad \text{H} \\
\text{H}_2\text{N} & \quad \text{C} \\
& \quad \text{NH}_2
\end{align*}
\]

\[\text{HSO}_3\text{F} - \text{SO}_2\text{ClF} \quad \text{SbF}_5 \quad \text{NH}_2 \quad \text{C} \\
\quad \text{H}_2\text{N} \quad \text{NH}_2
\]

Mono-\(O\)-protonated carbamic acid 381 has been obtained by Olah, Prakash, and co-workers\(^{694}\) by protolytic ionization of \(\text{tert}\)-butyl carbamate [Eq. (3.107)]. The NMR chemical shifts observed in \(\text{HSO}_3\text{F} - \text{SO}_2\text{ClF}\) solution are at \(\delta^1\text{H} 6.41\) (2H, \(J_{\text{N-H}} = 96.5\) Hz) and \(\delta^{15}\text{N} 69.5\) (triplet, \(J_{\text{C-N}} = 97.1\) Hz), representing the \(\text{NH}_2\) group, and at \(\delta^{13}\text{C} 162.4\) (doublet, \(J_{\text{C-N}} = 28.4\) Hz), representing the cationic carbon. This latter peak is 5.3 ppm deshielded relative to the carbonyl carbon of \(\text{tert}\)-butyl carbamate. The GIAO-MP2-calculated NMR shift values deviate significantly from the experimentally observed values. \(O\)-Protonated carbamic acid was calculated to be more stable than \(N\)-protonated carbamic acid (MP2/6-31G* level), by only 3.3 kcal mol\(^{-1}\).

Further protonation of protonated carbamic acid to form isomeric diprotonated carbamic acids does not take place. Dication 382a was calculated\(^{694}\) to have a longer C–N bond compared to protonated carbamic acid (1.478 versus 1.312 Å). It is indicative of one positive charge localized on the \(\text{NH}_3\) group, and the second charge is delocalized on the \(\text{O} - \text{C} - \text{O}\) unit. In contrast, dication 382b is characterized by a shorter C–N and a longer C–O bond relative to protonated carbamic acid (1.288 versus 1.312 Å and 1.460 versus an average 1.303 Å, respectively) revealing a localized positive charge on oxygen and delocalization of the other positive charge on the \(\text{O} - \text{C} - \text{N}\) unit. Of the two isomeric dications, the \(N\)-protonated structure 382a was calculated by 17.5 kcal mol\(^{-1}\) to be more stable than dication 382b.

Diprotonated \(N,N\)-bis(carboxyl)-1,2-diaminoethane 383 was also generated by protolytic ionization\(^{694}\) [Eq. (3.108)]. The carbocationic carbon resonance found at
$\delta^{13}C$ 161.5 in HSO$_3$F–SO$_2$ClF solution is only 0.9 ppm shielded from that of protonated carbamic acid.

Protonation of ethyl N-methyl carbamate was also performed in HSO$_3$F–SO$_2$ClF and HSO$_3$F–SbF$_5$ solutions. Due to the hindered rotation about the C–N bond, two rotamers are formed [Eq. (3.109)]. The $^{13}C$ NMR spectra of the HSO$_3$F–SO$_2$ClF solution showed resonances at $\delta^{13}C$ 160.4 assigned to the major trans isomer (384a) and at $\delta^{13}C$ 160.7 assigned to the minor cis isomer (384b). These resonances are shielded by 2.0 and 1.7 ppm, respectively, from that of protonated carbamic acid. Isomer 384a was found to be more stable by 5.4 kcal mol$^{-1}$ (MP2/6-31G* level). Again, the persistent diprotonated ethyl N-methyl carbamate dication was not detected. Likewise, only the O-monoprotonated cation was identified in the protonation of methyl carbamate.

Since nitrogen is a better electron donor than oxygen, in cationic derivatives of imines the contribution of the aminomethyl cation structure 385b, compared with that of the iminium ion resonance form 385a, is small. The same also applies to amidines (386) and guanidines (387).
Acidic iminium ions (385, \( R = H \)) are usually prepared by the protonation of compounds with \( C-N \) double bond such as imines\(^{542,696}\) [Eq. (3.110)] and ketoximes.\(^{542}\) The nonequivalence of the two \( C \)-methyl groups below \(-20^\circ C\) indicated that in cation 388 the rotation about the \( C=N \) bond is slow on the NMR time scale.\(^{696}\)

388

Olah and co-workers\(^{666}\) also reported the calculated structures of protonated methyleniminium cations using \textit{ab initio} methods (MP2/6-311+G** level). Both the \( N \)-protonated (389) and \( C \)-protonated (390) dications are minima on the potential energy surface, but the \( \text{NH}_3 \)-substituted methyl cation 389 is more stable than the \( 3e-2e \) bonded structure 390, by 27.6 kcal mol\(^{-1}\). Structure 389 was detected by charge stripping mass spectrometry by Schwarz and co-workers.\(^{697}\) Structures and energies of dications derived by protonation of methyl- and dimethyliminium ions have recently been calculated (MP2/6-311+G** level).\(^{698}\) Both the \( C \)-protonated and \( N \)-protonated dications were identified as minimum structure. However, the \( N \)-protonated isopropyliminium ion 391 (carbenium ammonium dication) was found to be more stable by 20.8 kcal mol\(^{-1}\), even though the formal cationic centers are adjacent.

Minkwitz et al.\(^{699}\) have prepared dichloromethyleneiminium salts 392 [Eq. (3.111)] and made vibrational and NMR spectroscopic characterization. They have also reported the X-ray crystal structure of the \( \text{Cl}_2 \text{C} = \text{NH}_2^+ \) and \( \text{Cl}_2 \text{C} = \text{NH} \text{Cl}_3^+ \) hexachloroantimonates. In the solid state the \( \text{Cl}_2 \text{C} = \text{NH} \text{Cl}_3^+ \) cation and the \( \text{SbCl}_6^- \) anion have one short H···Cl contact (2.313 Å).\(^{700}\) The cation framework is planar with \( C-N \) bond lengths of 1.488 and 1.280 Å. The latter value compares well with the bond distance of 1.268 Å in cation \( \text{Cl}_2 \text{C} = \text{NH}_2^+ \).\(^{699}\)

392

A number of methods, including alkylation,\(^{701,702}\) acylation,\(^{703}\) and halogena-
tion,\(^{704}\) are available for the synthesis of nonacidic iminium ions. \( N \)-Trifluoromethyl-
substituted iminium ions have been obtained by Minkwitz and Lamek\(^{704}\) using a

variety of approaches (Scheme 3.12).
1H, 13C, 15N NMR and ab initio/IGLO/GIAO-MP2 study of mono-, di-, tri-, and tetraprotonated guanidine have been performed by Olah, Prakash, and co-workers. Guanidinium ion 393 prepared according to a literature procedure [Eq. (3.112)] and isolated as the sulfate salt shows a broad peak in its 1H NMR spectrum (δ1H 6.6), a peak in its 13C NMR spectrum (δ13C 157), and a peak in its 15N NMR spectrum (δ15N 74). In agreement with previous calculations, guanidinium ion has a propeller-shaped structure of C3 symmetry (MP2/6-31G* level). The equivalence of the 15N NMR peaks indicates that no further protonation of ion 393 to form long-lived diprotonated guanidinium dication occurs at these acidities (H2SO4 and CF3SO3H at room temperature, and HSO3F–SO2ClF at −40°C). Cation 393 is, however, readily further protonated to diprotonated guanidinium dication 394 in substantially more acidic Magic Acid solution [Eq. (3.112)].

In its 1H NMR spectrum, dication 394 exhibits an NH3+ peak (δ1H 6.76) and two peaks at δ1H 6.32 and 6.09 in agreement with data previously reported by Olah and White. The 13C NMR spectrum consists of a peak centered at δ13C 148.9, and it is shielded by 8 ppm from that of the guanidinium cation. The calculated bond distances—that is, a longer C–NH3 and a shorter C–NH2 bond compared to guanidinium ion—indicate that one of the positive charges is localized on NH3 group, and the second charge is delocalized among H2N–C–NH2. Previous calculations on diprotonated urea and thiourea showed a similar pattern of charge distribution. No further protonation of the dication could be achieved. The calculated structure of triprotonated guanidine indicates that two of the positive charges are localized on two NH3 groups and the third charge is delocalized over the amiocarbenium moiety (395) resembling an ammonium–iminium structure. Formation of trication 395 is endothermic by 70.1 kcal mol−1. GIAO-MP2 calculations indicate a deshielding effect of 6.3 in the 13C NMR chemical shift of the trication compared to the dication.
Deshielding was also found in the $^{15}\text{N}$ NMR chemical shifts. Structure 396 is the calculated structure of tetraprotonated guanidine. The four localized positive charges are, obviously, highly unfavorable.

Even diazomethane has been protonated$^{708}$ in the superacid media. In Magic Acid media, both methyldiazonium ion 397 as well as $N$-protonated diazomethane 398 are formed [Eq. (3.113)].

$$\text{CH}_2\text{N}_2 + \text{HSO}_3\text{F} - \text{SbF}_5 \rightarrow \text{CH}_3\text{N}_2^+ + \text{CH}_2=\overset{\ddagger}{\text{N}}=\overset{\ddagger}{\text{NH}}$$

(3.113)

A series of 2-azaallenium ions have been prepared and characterized including X-ray crystal structures.$^{709,710}$ Charge delocalization and, consequently, structural features depend significantly on substituents. In many cases, the contribution of the allenium ion form 399a is more significant.

Meerwein et al.$^{711}$ reported $N$-alkylnitrilium salts and Olah and Kiovsky$^{712}$ have studied protonated alkyl nitriles and hydrogen cyanide generated in $\text{HSO}_3\text{F} - \text{SbF}_5$ solution at low temperatures. $^{13}\text{C}$ and $^{15}\text{N}$ NMR characterization of the cations 400 showed that the nitrile carbon is $sp$-hybridized and, therefore, nitrilium ions are linear species. This conclusion is supported by theoretical studies$^{713}$ and X-ray crystal structure$^{714}$ of nitrilium ion 401, indicating linear arrangement and triple-bond character of the $\text{C} - \overset{\ddagger}{\text{N}}$ bond.

A variety of dications have recently been prepared and characterized by X-ray diffraction. The tetrakis(dimethylamino)ethylene dication 402 has been generated by
two-electron oxidation of tetrakis(dimethylamino)ethylene\textsuperscript{715} [Eq. (3.114)]. Theoretical calculations for the ethylene dication predict $D_2d$ geometry.\textsuperscript{716,717} In agreement with this prediction, X-ray characterization of dication 402 showed that the two halves of the ion rotate by up to 76°. Furthermore, the planar Me$_2$N groups are twisted out of the two CCN$_2$ planes. The C–C bond lengths (1.51 Å), whereas the C–N bonds significantly shorten (1.30–1.33 Å).

\begin{equation}
\text{Me}_2\text{N} \equiv \text{C} \equiv \text{NMe}_2 \quad \text{Cl}_2 \text{ or Br}_2 \quad \text{CHCl}_3 \quad -10^\circ\text{C} \quad \text{Me}_2\text{N} \equiv \text{C}^+ \equiv \text{NMe}_2
\end{equation}

Cationic formamidinium derivatives have also been prepared and characterized.\textsuperscript{718,719} The 1,1,3,3-tetrakis(alkylamino)allyl cation 403 formed according to Eq. (3.115) gives dication 404 after protonation. In cation 403, both C–C and C–N bonds are significantly reduced compared with the corresponding single bonds. One of the C–N bonds is significantly longer than the others (1.41 Å versus 1.34 Å). This is presumably due to the unfavorable steric arrangement of one of the attached tert-butyl groups resulting in less favorable delocalization. The allyl bonds are, consequently, nonsymmetric (1.38 and 1.42 Å). The C–C bonds of dication 404 are considerably longer (1.50 and 1.52 Å), the C–C–C angle is close to tetrahedral (112.5°), and the CCN$_2$ planes are inclined at an angle of 82° compared with 28° in cation 403. These changes indicate that delocalization is confined to the outer atoms. The barrier of rotation about the amidine C–N bond was estimated from variable temperature NMR data to be \(\Delta G^\circ \approx 18 \text{ kcal mol}^{-1}\).

\begin{equation}
\text{RNH}_2 \quad \text{CHCl}_3 \quad -20^\circ\text{C} \quad \text{tertBuHN} \quad \text{NHtertBu} \quad \text{HCl} \quad \text{ZnCl}_2 \quad \text{RHN} \quad \text{HNR} \quad \text{Y} = 2 \text{ Br, PhB}_2\text{Cl, HgCl}_4, 2 \text{ TfO}
\end{equation}

A series of diprotonated bisguanidinium dications 405 have been synthesized and characterized.\textsuperscript{720,721} X-ray crystal structure analysis shows that the C=N and C–NMe$_2$ bonds have very similar bond lengths (1.326–1.341 Å and 1.331–1.343 Å, respectively). This indicates that each guanidinium moiety is highly symmetrical because of efficient charge delocalization. Crystal packing forces, in turn, result in significant differences in N–C–C–C torsion angles and angles between the planes of guanidinium units.
3.4.17. Carbocations Complexed to Metal Atoms

Organometallic cations, in which an organic ligand is coordinated to a metal atom bearing a unit positive charge, constitute a significant class of compounds. Most common of these are the \( \pi \)-allylic \( \text{eq. (3.116)} \) and \( \pi \)-dienyl, \( \pi \)-cycloheptatrienyl, and \( \pi \)-cyclooctatetraenyl systems. Generally, metal atoms of low oxidation states are involved in complexing the electron-deficient ligands. The usual metals involved are transition metals such as Fe, Cr, Co, Rh, Ir, Pd, and Pt.

Since their discovery, cobalt and, in particular, cationic dicobalt propargyl complexes have played an important role in organic synthesis. The X-ray structure of such a complex has recently been reported. Similar heterobimetallic complexes have also been synthesized. IR and NMR spectroscopic data suggest that in complex 412 the stabilized \( \text{HC} \equiv \text{CCMe}_2^+ \) ions are \( \pi \)-coordinated to Mo or W atoms and not to nickel. A recent example is the \( \alpha \)-CF\(_3\) substituted 413 cation stabilized by the bimetallic Co–Co cluster. Unlike the uncomplexed 2-alkynylbornyl cations, bimetallic (Mo,Mo and Co,Mo) 2-propynylbornyl cation complexes related to cations 413 were found not to undergo Wagner–Meerwein rearrangement. According to X-ray data, the 2-bornyl cation leans toward Mo in the mixed-metal Mo,Co complex. The synthesis and X-ray structure of a dicationic dimolybdenum complex was also reported.
Cr(CO)$_3$ is also known to strongly stabilize carbocations. Theoretical studies for benzyl cations are abundant.\textsuperscript{733} Hoffmann and co-workers\textsuperscript{734} proposed that conformation 414a would be more stable by approximately 6.8 kcal mol$^{-1}$ than its rotamer. According to recent computations (B3LYP), however, the energy barrier is negligible (0.2 kcal mol$^{-1}$).\textsuperscript{735} An interesting feature of complex 414 is that the benzylic carbon bends down to coordinate to Co; that is, the contribution of resonance form 414b is significant.\textsuperscript{735–737} Consequently, the complex may be better viewed as a pentadienyl cation with an exocyclic double bond. The bending angle, however, decreases with increasing substitution at the benzylic carbon.

Harman and co-workers\textsuperscript{738} reported the synthesis of arenium cations stabilized by Os complexation (for example, 415) via protonation with triflic acid of [Os(NH$_3$)$_5$(Ar)](OTf)$_2$ complexes (Ar = benzene, toluene, xylenes, naphthalene, anthracene).

There are also several carbocations that have an $\alpha$-$\pi$-complexed organometallic system. Cation 416 was easily prepared as the hexachloroantimonate salt\textsuperscript{739} [Eq. (3.117)].

\begin{equation}
\text{Fe(CO)$_3$CH$_2$Cl} + \text{SbCl$_5$} \rightarrow \text{Fe(CO)$_3$CH$_2^+$}
\end{equation}

The most notable of these ions are $\alpha$-ferrocenyl carbenium ions such as 417, 418, and 419. As shown, cation 417 has a transoid conformation with a C–C$^+$–C bond angle of 127°.\textsuperscript{740} The ferrocenyl rings are bent at the carbocation center to reduce the distance between the Fe atoms and the carbocation carbon. $^{13}$C NMR data for cation 418 indicate significant charge delocalization attributed to either $p$–$\pi$ conjugation resulting in partial double bond character of the C$^+$–ferrocenyl bond or direct C$^+$–Fe interaction.\textsuperscript{741} Allylic cation 419 was generated by protonation with HBF$_4$ of the corresponding alcohol and was fully characterized.\textsuperscript{742} X-ray structure analysis of the
tetrafluoroborate salt has found that the 1,3-ferrocenyl units are twisted (9.7–21.9°) and the cyclopentadienyl rings are planar but not parallel. Furthermore, similar to other α-ferrocenyl carbenium ions, the ferrocenyl units tilt toward the cationic allyl moiety (2.8–4.9 Å), indicating a weak interaction (Fe–α-C⁺ bond distances = 2.83 and 3.04 Å, α-C⁺–ferrocene bond angles = 4.8° and 15.7°).

As mentioned, the facile ring opening of the cyclopropyl cation 44 to the energetically more favorable allyl cation 45 prevented direct observation [see Eq. (3.29)]. Since the ferrocenyl group is a superstabilizing group for α-carbocationic centers, Olah, Prakash, and co-workers[^743] ionized the 420 trimethylsilyl ether to find that upon heating, the intermediate protonated ether transformed to cation 421 [Eq. (3.118)]. The carbon signals of the methylene carbons of the cyclopropyl group (δ^13C 7.6) and the resonance of the carbocationic center at δ^13C 117.1 indicate extensive charge delocalization into the ferrocenyl moiety.

3.5. EQUILIBRATING (DEGENERATE) AND HIGHER (FIVE OR SIX) COORDINATE (NONCLASSICAL) CARBOCATIONS

3.5.1. Alkonium Ions (Protonated Alkanes C\(_n\)H\(_{2n+3}\)⁺)

As recognized in the pioneering work of Meerwein, Ingold, and Whitmore,[^10,12,18,19,744] trivalent alkyl cations (C\(_n\)H\(_{2n+1}\)⁺) play important roles in the acid-catalyzed transformations of hydrocarbons as well as various electrophilic and Friedel–Crafts-type reactions. Trivalent alkyl cations can directly be formed by the ionization of lone-pair (nonbonded electron pair) containing precursors (n-bases) such as alkyl halides, alcohols, thiols, and so on, or by protonation of singlet carbenes or olefins.
Protonated alkanes (C\textsubscript{n}H\textsubscript{2n+3}\textsuperscript{+}) also play a significant role in alkane reactions. Saturated hydrocarbons can be protonated to alkonium ions, of which the methonium ion CH\textsubscript{5}\textsuperscript{+}, 422 [Eq. (3.119)] is the parent, and formation of these pentacoordinate carbocations involves two-electron three-center (2e–3c) bonds. The dotted lines in the structure symbolize the bonding orbitals of the three-center bonds [Eq. (3.119)]; their point of junction does not represent an additional atom.

\[ \text{H} + \text{CH}_5\textsuperscript{+} \rightleftharpoons \text{CH}_3\textsuperscript{+} + \text{H}_2 \]  

(3.119)

3.5.1.1. The Methonium Ion (CH\textsubscript{5}\textsuperscript{+}). The existence of the methonium ion (CH\textsubscript{5}\textsuperscript{+}, 422)\textsuperscript{745} was first indicated by mass spectrometric studies of methane\textsuperscript{746} at relatively high source pressures—that is, molecular–ion reaction between a neutral CH\textsubscript{4} and a proton. Isotope exchange and collisional association in the reactions of CH\textsubscript{3}\textsuperscript{+} and its deuteriated analogs with H\textsubscript{2}, HD, and D\textsubscript{2} have also been studied by mass spectrometry using a variable-temperature ion-flow method.\textsuperscript{747} The chemistry of methane and homologous alkanes (e.g., hydrogen–deuterium exchange and varied electrophilic substitutions in superacidic media) pointed out the significance of alkonium ions in condensed state chemistry. The energy of dissociation of CH\textsubscript{5}\textsuperscript{+} to CH\textsubscript{3}\textsuperscript{+} and H\textsubscript{2} is known experimentally\textsuperscript{748} to be 40 kcal mol\textsuperscript{-1} and calculated as 34.7 kcal mol\textsuperscript{-1} by \textit{ab initio} MO theory [MP4(SDQ)/6-311G**+ZPE].\textsuperscript{749}

Direct spectroscopic observation of CH\textsubscript{5}\textsuperscript{+} in the condensed state is difficult, because the concentration of the ion even in superacidic media at any time is extremely low. The matrices of superacids, such as HSO\textsubscript{3}F–SbF\textsubscript{5} or HF–SbF\textsubscript{5} saturated with methane, were studied by ESCA\textsuperscript{750} at \textdegree{}180\textdegree{}C, and the observed carbon 1s binding energy differing by less than 1 eV from that of methane is attributed to CH\textsubscript{5}\textsuperscript{+}. Neutral methane has practically no solubility in the superacids at such low temperature of the experiment, and at the applied high vacuum (10\textsuperscript{-9} torr) it would be pumped out of the system. The relatively low 1s carbon binding energy in CH\textsubscript{5}\textsuperscript{+} is in good accord with theoretical calculations,\textsuperscript{751} indicating that charge density is heavily on the hydrogen atoms and the five-coordinate carbon carries relatively little charge.

There are four possible structures of the methonium ion (C\textsubscript{5v}, C\textsubscript{2v}, C\textsubscript{4v}, or D\textsubscript{3h} symmetry) (Figure 3.18). C\textsubscript{5} has two structures: the eclipsed C\textsubscript{5}(e) and the staggered

![Figure 3.18. Methonium ion structures of various symmetries.](image-url)
Cs(s) conformation. The latter is the transition state for rotation of the H₂ moiety of 3c–2e bond. These structures resemble a complex between CH₃⁺ and a hydrogen molecule, resulting in the formation of a 3c–2e bond. Of the possible structures, Olah, Klopman, and Schlosberg⁷⁵¹ suggested preference for the Cs front-side protonated form.

Preference for this form was based on consideration of the observed chemistry of methane in superacids (hydrogen–deuterium exchange and, more significantly, polycondensation indicating ease of cleavage to CH₃⁺ and H₂) and also on the basis of self-consistent field (SCF) calculations.⁷⁵¹ More extensive calculations including ab initio⁷⁴⁹,⁷⁵²–⁷⁵⁴ utilizing “all geometry” parameter search confirmed the favored structure of Cs symmetry. This structure is about 3.7 kcal mol⁻¹ more stable than the structure of C₄v symmetry, which in turn is about 11.7 kcal mol⁻¹ more stable than the trigonal bipyramidal D₃h symmetry structure.⁷⁴⁹ Interconversion of stereo-isomeric forms of CH₅⁺ is obviously possible by a pseudorotation process. Muetterties suggested⁷⁵⁵ that stereoisomerization processes of this type in pentacoordinated compounds could be termed “polytopal rearrangements.” However, it is preferable to call intramolecular carbonium ion rearrangements as “bond-to-bond rearrangements” since these are not limited to equivalent bonds in the case of the higher homologs of CH₅⁺ (see subsequent discussion).

More sophisticated quantum mechanical calculations have been performed on CH₅⁺ during the last 20 years. The Cs symmetrical form is the energy minimum structure [MP2(FU)/6-31G** level of theory],⁷⁵⁶ and frequency calculations at the same level showed that no other forms are minima on the potential energy surface. Structure C₂v was located as a transition structure for intramolecular hydrogen transfer. The C–H and H–H bond distances in the 3c–2e interactions [calculated at the MP2(FU)/6-311++G(2df,2pd) level] are 1.180 Å and 0.980 Å, respectively.⁷⁵⁶ Single-point energies, however, showed that Cs is only 0.86 kcal mol⁻¹ more stable than C₂v [QCISD(T)/6-311++G(3df,3pd)//MP2(FU)/6-311++G(2df,2pd) level]. After corrections for zero point vibrational energies, however, Cs and C₂v have essentially the same energies at absolute zero temperature. As a consequence, hydrogen scrambling in Cs, in accordance with experimental observations is a very facile process.

The Cs and C₂v structures have been reinvestigated by Schleyer and co-workers⁷⁵⁷ at even higher-level ab initio theory. Changes in geometry were found to be very small, implying that the optimizations are essentially converged within theoretical limits. The differences in energies between the structures increasingly vanish at the most sophisticated levels and hydrogen scrambling becomes an essentially barrierless process. CH₅⁺ was concluded to be a fluxional molecule and thus a rather unique species. Protonated methane is not the nonclassical carbocation prototype, but CH₅⁺ is unique.⁷⁵⁷–⁷⁵⁹ A more recent study has used quantum diffusion Monte Carlo techniques on an interpolated potential surface constructed from CCSD(T)/aug'-cc-pVTZ ab initio data.⁷⁶⁰ The ground state of CH₅⁺ was found to be significantly more symmetric than its global minimum energy structure. The zero-point motion of CH₅⁺ renders all five protons equivalent in the ground state; that is, the ground state structure of CH₅⁺ is more symmetric than the Cs global minimum energy configuration.
Marx and Parrinello performed an extensive *ab initio* electronic structure calculation (Car–Parrinello simulation\(^{761}\)) also including the quantum effects and showed that a preference for the \(C_s\) quantum ground state does exist.\(^{762}\) Furthermore, a small but definite barrier for hydrogen equilibration was found to exist. The preferred \(C_s\) symmetrical structure of \(\text{CH}_5^+\) was also reconfirmed by Kutzelnigg and co-workers\(^{763}\) [high-level CCSD(T)-R12 with large basis sets].

Attempts have been made to observe and experimentally determine the structure of \(\text{CH}_5^+\) in the gas phase and study it in the condensed state using IR spectroscopy,\(^{764,765}\) pulse electron-beam mass spectrometry,\(^{766}\) and Fourier transform ion cyclotron resonance mass spectrometry (FT–ICR MS).\(^{767}\) However, an unambiguous structure determination was unsuccessful. Retardation of the degenerate rearrangement was achieved by trapping the ion in clusters with \(\text{H}_2\), \(\text{CH}_4\), \(\text{Ar}\), or \(\text{N}_2\).

The IR spectrum of the \(\text{CH}_5^+\) ion solvated by a hydrogen molecule \([\text{CH}_5^+\text{(H}_2)\text{]}\), \(^{423}\) has been reported by Bo and Lee.\(^{764}\) The frequency of the stretching band centered at 2966 cm\(^{-1}\) matches the calculated frequency of \(^{423}\) containing the \(C_s(e)\) structure by the *ab initio* method.\(^{768}\) IR spectra of solvated ions \(\text{CH}_5^+\text{(H}_2)\text{n}\) \((n = 1–6)\) were also disclosed.\(^{769}\) Data indicated the scrambling of \(\text{CH}_5^+\) through large-amplitude motions such as the \(\text{CH}_3\) internal rotation and in-plane wagging motion. Attachment of solvent \(\text{H}_2\) molecules to the core ion slowed the scrambling, and binding three \(\text{H}_2\) molecules to the \(\text{CH}_5^+\) core ion ultimately resulted in the complete freezing of scrambling motions.

Protonated methane has a complex high-resolution IR spectrum,\(^{765}\) which is not inconsistent with theoretical predictions. Because the three nonequivalent equilibrium structures \([C_s(e), C_s(s), \text{and } C_{2v}]\) have nearly identical energies and its five protons scramble freely, the ion shows an unusual vibrational and rotational behavior. However, no assignment or even qualitative interpretation was offered. Marx and co-workers\(^{770,771}\) have recently disclosed a comprehensive study of the properties of protonated methane using laser-induced reaction technique. A comparison of the experimental infrared spectrum of bare \(\text{CH}_5^+\) at \(-110\) K to finite-temperature spectra calculated by *ab initio* molecular dynamics supports the fluxionality of the protonated methane cation. Interestingly, hydrogen scrambling and internal rotation of the \(\text{H}_2\) moiety could be computationally frozen out, which allowed the interpretation of the observed IR spectrum. Three distinct, well-separated peaks of \(\text{C–H}\) stretching modes involving the carbon nucleus and the protons that form the \(\text{H}_2\) moiety, along with the hydrogens engaged in the \(\text{CH}_3\) tripod, lend experimental support to three-center
two-electron bonding. Hydrogen scrambling was suggested to result from softening of a mode that involves bending of the H$_2$ moiety relative to the CH$_3$ tripod.

Pulse electron-beam mass spectrometry was applied by Kebarle, Hiraoka, and co-workers\textsuperscript{766,772} to study the existence and structure of CH$_5^+(\text{CH}_4)_n$ cluster ions in the gas phase. These CH$_5^+(\text{CH}_4)_n$ clusters were previously observed by mass spectrometry by Field and Beggs.\textsuperscript{773} The enthalpy and free energy changes measured are compatible with the C$_s$ symmetrical structure. Electron ionization mass spectrometry has been recently used by Jung and co-workers\textsuperscript{774} to explore ion–molecule reactions within ionized methane clusters. The most abundant CH$_5^+(\text{CH}_4)_n$ cluster is supposed to be the product of the intracluster ion–molecule reaction depicted in Eq. (3.120) involving the methane dimer ion 424.

\[
\text{CH}_n\text{H}_n\text{CH}_4\text{H}_n \rightleftharpoons \text{CH}_n\text{H}_n\text{CH}_5\text{H}_n \rightleftharpoons \text{CH}_n\text{H}_n\text{CH}_3 \rightleftharpoons \text{CH}_n\text{CH}_3 \quad (3.120)
\]

Isotopic protonated (deuteriated) methanes were generated under various pressure conditions, and their reactivity toward ammonia was studied by FT–ICR mass spectrometry.\textsuperscript{767} Competition between proton and deuterium transfer from protonated perdeuteriomethane and deuteriated methanes to ammonia shows chemically distinguishable hydrogens. The results allowed to conclude that the chemical behavior of protonated methane appears to be compatible with the theoretically predicted stable structure with C$_s$ symmetry, involving a two-electron three-center bond. Interconversion of this structure due to exchange between one of the two associated hydrogens and one of the remaining hydrogens appears to be fast, which is induced by interactions with the chemical ionization gas.

As early as 1972, Libby and co-workers\textsuperscript{775} studied radiolysis by $\gamma$-rays of solid methane in liquid argon at 77 K and detected the formation of polymers. The CH$_5^+$ ion, most probably formed according to Eq. (3.121), may be involved in the process, whereas subsequent ion–molecule reactions followed by neutralization lead to heavier hydrocarbons [Eq. (3.122)].

\[
\text{CH}_4^+ + \text{CH}_4 \rightleftharpoons \text{CH}_5^+ + \text{CH}_3^- \quad (3.121)
\]

\[
\text{CH}_4 + \text{C}_n^+\text{H}_{2n+1} \rightleftharpoons \text{H}_2 + \text{C}_n^+\text{H}_{2n+3} \quad (3.122)
\]

Sommer and co-workers\textsuperscript{776} have used experimental techniques (determining secondary kinetic deuterium isotope effects) and computational (DFT and high-level \textit{ab initio}) methods to study methane activation in HF–Sbf$_5$. The methonium ion solvated by HF (425) was found to be the potential energy minimum. The unsolvated superacid H$_2$F$^+$ is the only species strong enough to protonate methane in a barrierless process (B3LYP/BS2 and MP2/BS1 levels). The potential energy of the activated complex (426) for the exchange process was calculated to be only 1.9 kcal mol$^{-1}$ higher than that of the strongly HF-bonded product CH$_5^+$ ion (425). The (HF)$_x$-solvated H$_2$F$^+$ superacid ($x = 1–4$) is not able to yield stable solvated methonium ions,
but it participates in the transition states of the exchange in which \( \text{CH}_5^+ \) ions are solvated by \((\text{HF})_x\).

![Diagram](425)

![Diagram](426)

On the basis of the information discussed above, the \( \text{CH}_5^+ \) ion appears to be a fluxional species that undergoes rapid, very low-energy bond-to-bond rearrangements as postulated by Olah et al.\(^{751}\) as early as 1969. The core protonated methane, however, is still best represented by the \( C_s \) symmetry ground-state structure and can be considered the parent carbonium ion.

Schleyer and co-workers\(^{777,779}\) have calculated by \textit{ab initio} methods the geometry of several lithiated analogs of \( \text{CH}_5^+ \), including structures \( 427 \) and \( 428 \). Both \( \text{CH}_3\text{Li}_2^+ \) and \( \text{CLi}_5^+ \) have been observed by mass spectrometry.

![Diagram](427)

![Diagram](428)

Schmidbaur and co-workers\(^{780–783}\) have prepared the monopositively charged gold complexes \([\text{L} \text{Au}_5\text{C}]^+\)\(^{429}\), which are the substituted analogs of \( \text{CH}_5^+ \). Considering the isolobal relationship (i.e., similarity in bonding) between \( \text{L} \text{Au}^+ \) and \( \text{H}^+ \), complexes \( 429 \) represent the isolobal analog of \( \text{CH}_5^+ \). The structure is of these compounds were determined by various experimental techniques (analytical and spectroscopic identifications, single-crystal X-ray crystallography). The X-ray data of the \( [(\text{Ph}_3\text{PAu})_5\text{C}]^+\text{BF}_4^- \) complex show a trigonal bipyramidal structure (\( C_3 \) symmetry). This was the first isolation and X-ray determination of an analog of \( \text{CH}_5^+ \), followed by the preparation and characterization of the pyramidal complex \( 430 \).\(^{784}\)

![Diagram](429)

![Diagram](430)

Boron and carbon are consecutive first-row elements. Consequently, pentacoordinate monopositively charged carbonium ions are isoelectronic with the corresponding neutral pentacoordinate boron compounds; that is, the \( \text{BH}_5 \) molecule is isoelectronic with \( \text{CH}_5^+ \). Within this context, it is interesting to refer to the five-coordinate...
square-pyramidal gold cation complex \(\{[\text{Cy}_3\text{PB}(\text{AuPPh}_3)_4]\}^{+}\), \(\text{Cy} = \text{cyclohexyl}\) \(431\) reported and studied by Schmidbaur and co-workers,\(^{781,785}\) which is the isolobal analog of BH\(_5\). The symmetry of the PB(AuP)\(_4\) skeleton of cation \(431\) is close to \(C_{4v}\), and the four gold atoms are arranged in a slightly distorted and folded square capped by the boron atom with an apical \(\text{Cy}_3\text{P}\) ligand. The short Au–Au distances (2.82 Å average) indicate bonding interactions between neighboring Au atoms.

\text{Ph}_3\text{PAu}
\end{array}
\]

\(431\)

3.5.1.2. Multiply Protonated Methane Ions and Their Analogs. In addition to the involvement in a single 2e–3c bond formation, carbon is also capable of simultaneously participating in two 2e–3c bonds in some carbocations. Diprotonated methane (protiomethonium dication, CH\(_6^2+\)) is the parent of such carbocations.

The \(C_{2v}\), symmetrical structure (\(432\)) of diprotonated methane with two stabilizing orthogonal 2e–3c interactions was shown by quantum mechanical calculations (\textit{ab initio} methods)\(^{786,787}\) to be the only minimum on the potential energy surface. The other structures (\(433–436\)), in turn, were calculated to be saddle points on the potential energy surface. These were found to be 5.7, 12.0, 17.4, 41.5, and 35.2 kcal mol\(^{-1}\), respectively, higher in energy than structure \(432\) (HF/6-31G**//HF/6-31G* level). At the HF/6-31G* level, the C–H bond length of each of the 2e–3c interactions is considerably longer than that of 2e–2c bonds (1.208 Å and 1.123 Å, respectively). The H–H bond length in 2e–3c interactions is 0.972 Å. On the basis of these data, structure \(432\) can be visualized as a complex of H\(_2\) with the \(p\)-orbital of the carbon atom of the planar \(C_{2v}\) symmetrical CH\(_6^{2+}\) dication. Olah et al.\(^{788}\) have recently recalculated CH\(_6^{2+}\) at even higher theoretical levels [MP4(SDTQ)/6-311G**//MP2/6-31G**]. C–H and H–H bond lengths in 2e–3c interactions were found to be 1.202 and 1.018 Å, respectively.

\]

\(432\)

The dication (C\(_6\)Me\(_6\))\(^{2+}\) (\(437\)) and the CLI\(_6^{2+}\) dication (\(438\)) are two additional six-coordinate carbon-containing species. Ion \(437\) was observed by Hogeveen and
Kant and has a pyramidal structure (see Section 3.5.4.2). Calculations carried out for $\text{C}^2 \text{Li}_{6}^2^+$ (438) show a preference for the octahedral structure. Furthermore, similar to the five-coordinate $\text{CH}_5^+$ analog gold complexes, the dipositive charged [(LAu)$_6$C]$^2^+$ gold complexes 439, containing a six-coordinate carbon atom have also been prepared and characterized by Schmidbaur and co-workers. According to X-ray data, complex 439 ($L = \text{PPh}_3$), which is an isobal mimic of $\text{CH}_6^2^+$, has a distorted octahedral structure with Au–Au edges in the range 2.887–3.226 Å. Relativistic electronic structure calculations (LCGTO-LDF method) for the corresponding $\text{PH}_3$- and $\text{PMe}_3$-ligated models showed that the complexes are stable with respect to the loss of an AuPR$_3^+$ ligand.

Six-coordinate dipositively charged carbocations are isoelectronic with the corresponding monopositively charged hexavalent boron compounds. The parent six-coordinate boronium ion $\text{BH}_6^+$, isoelectronic with $\text{CH}_6^2^+$, was generated in the gas phase by DePuy et al., and Olah and coworkers studied simultaneously its structure and energetics. The $C_2v$ symmetric form isostructural with $\text{CH}_6^2^+$, containing two $2e$–$3c$ interactions and two $2e$–$2c$ bonds (see structure 432), was found to be the only stable minimum for $\text{BH}_6^+$ [MP2/6-31G** level and B3LYP/6-31++G (3df,2pd) level].

Olah and Rasul have reported ab initio calculations for triprotonated methane (diprotiomethonium trication, $\text{CH}_7^{3^+}$). For the parent seven-coordinate $\text{CH}_3^{3^+}$ carbocation the $C_3v$ symmetrical form (440) was found to be the only stable minimum (MP2/6-31G** level). It is a propeller-shaped molecule and can be visualized as a complex between $\text{CH}^3^+$ and three hydrogen molecules, resulting in the formation of three $2e$–$3c$ interactions with the hydrogen atoms bearing the positive charges (NBO charge calculation). It appears that strong bonding interactions in the cation can counter the substantial charge–charge repulsion. The C–H bonds in the $2e$–$3c$ interactions are slightly longer (1.282 and 1.277 Å) than bond distances in the $\text{CH}_5^+$ structure (1.181 Å) at the same level of theory. Similarly, the H–H bond distance in the $2e$–$3c$ interactions (1.085 Å) is longer than that in the free hydrogen molecule (0.734 Å) at the same theoretical level and is also slightly longer than that found in $\text{H}_2^+$ (1.031 Å). The transition structure for intramolecular hydrogen transfer (441) lies only 0.7 kcal mol$^{-1}$ higher in energy than structure 440, indicating very facile intramolecular proton transfer. In accordance with expectations, various dissociation reactions of $\text{CH}_7^{3^+}$ are highly exothermic processes (data calculated at G2 theory) (Scheme 3.13).
A search was also made for the minimum-energy structure for the octacoordinate carbocation complex tetraprotonated methane (CH$_8^{4+}$). This can be viewed as four dihydrogen units complexed with the tetrapositively charged C$_4^{4+}$ cation and can be compared with the CH$_3^{+}$ + 3H, CH$_2^{2+}$ + 2H, CH$_3^{-}$ + H$_2$ complexes in CH$_7^{3+}$, CH$_6^{2+}$, CH$_5^{+}$ carbocations, respectively. It appears, however, that charge–charge repulsions have reached a prohibitive limit, since efforts at MP2/6-31G** level proved to be futile; that is, CH$_8^{4+}$ remains even computationally elusive.

A search was also made for the minimum-energy structure for the octacoordinate carbocation complex tetraprotonated methane (CH$_8^{4+}$). This can be viewed as four dihydrogen units complexed with the tetrapositively charged C$_4^{4+}$ cation and can be compared with the CH$_3^{+}$ + 3H, CH$_2^{2+}$ + 2H, CH$_3^{-}$ + H$_2$ complexes in CH$_7^{3+}$, CH$_6^{2+}$, CH$_5^{+}$ carbocations, respectively. It appears, however, that charge–charge repulsions have reached a prohibitive limit, since efforts at MP2/6-31G** level proved to be futile; that is, CH$_8^{4+}$ remains even computationally elusive.

3.5.1.3. Varied Methane Cations. The methane molecular ion (methane radical cation, CH$_4^{+}$), the parent ion in mass spectrometry, and the methane dication (CH$_4^{2+}$) are of great significance and have been studied both experimentally and theoretically.$^{800-802}$ Recent advanced studies have shown that the methane radical cation, CH$_4^{+}$ has a fivecoordinate planar structure as suggested in early calculations by Olah and Klopman.$^{800}$ The methane dication (CH$_4^{2+}$) with a lifetime of only $\Delta$$t$ = 3 ms$^{803}$ has been detected experimentally in the gas phase.$^{804-807}$ A square-planar $D_{4h}$ symmetrical structure was predicted by early calculations.$^{808,809}$ However, the planar but not square $C_{2v}$ symmetrical form (443) was shown to be the preferred structure by Wong and Radom.$^{810}$ The cation contains an $sp^2$-hybridized carbon, an empty $p$-orbital perpendicular to the plane of the molecule, and a $2e$–$3c$ interaction. It can be visualized as a complex of a hydrogen molecule weakly bounded by a $2e$–$3c$ bond to the CH$_2^{2+}$ core as shown by $ab$ initio calculations [MP2 and B3LYP levels with 6-311++G(2df,2pd) basis set].$^{811}$ The pentacoordinate CH$_5^{2+}$ radical dication was studied by Stahl
et al.\textsuperscript{807} by charge stripping mass spectrometry and the $C_s$ symmetric geometry (444) was rationalized by theoretical calculations.

The CH$_5^{3+}$ trication, which is formed by the removal of one electron from the CH$_5^{2+}$ radical dication, has been studied theoretically by Olah and Rasul.\textsuperscript{812} Only a single minimum was found on the potential energy surface (MP2/6-31G** level). This is the planar $D_{5h}$ symmetrical structure (445) with the five hydrogens bonded to the carbon atom sharing only six valence electrons and a vacant $p$-orbital perpendicular to the plane of the molecule. Another possible structure (446) with two $2e-3c$ bonds is not a minimum and converges to structure 445 upon optimization. The C–H bonds in trication 446 are electron-deficient and, consequently, weaker. Therefore, the bond lengths in structure 446 are longer (1.317 Å) than those in the $2e-3c$ C–H bonds of the $C_s$ structure of CH$_5^{+}$ (1.181 Å). Bonding interactions between adjacent hydrogens are negligible, since hydrogens are separated by 1.549 Å. The dissociation of CH$_5^{3+}$ to CH$_4^{2+}$ and H$^+$ is highly exothermic (274.6 kcal mol$^{-1}$), indicating that the CH$_5^{3+}$ trication is highly unstable. The search for the minimum energy structure of the CH$_6^{4+}$ tetracation was also unsuccessful.

Calculations on the structure and stabilities of helium-containing polyatomic ions\textsuperscript{813} were reported in the 1980s by Wilson and co-workers,\textsuperscript{814,815} Schleyer,\textsuperscript{816} and Radom and co-workers\textsuperscript{817} and more recently by Koch, Frenking, and co-workers.\textsuperscript{818,819} The quadruply charged tetrahelimiomethane tetracation CH$_4^{4+}$ shown by Radom and co-workers\textsuperscript{817} to be a remarkably stable species was first calculated by Schleyer.\textsuperscript{816} More recently, Olah et al.\textsuperscript{820} studied the CH$_4$He$^{2+}$ heliometonium dication, which is isoelectronic with CH$_5^{+}$. The $C_s$ symmetric form 447 is the only stable minimum, whereas the $C_{4v}$ symmetrical structure (448) is the transition state for hydrogen scrambling [MP2/6-31G* and MP2/6-311+G(2d,p) levels]. Structure 447, which may be considered as a complex between a neutral helium atom and methane dication CH$_4^{2+}$, contains one $2e-3c$ bond. Structure 447 is only 1.7 kcal mol$^{-1}$ more stable than structure 448 (MP2/6-31G**/MP2/6-31G** level). The energy difference between the two structures, however, disappears at the highest level of theory applied,
allowing very facile hydrogen scrambling.

The energetics of several dissociation paths of the CH₄He²⁺ dication was also calculated by the G2 method (Scheme 3.14). The first two processes are highly exothermic, but deprotonation has a significant kinetic barrier. The dissociation of CH₄He²⁺ into CH₄²⁺ and a neutral helium atom is endothermic. This provides a possibility to generate CH₄He²⁺ by reacting CH₄²⁺ with He in the gas phase.

3.5.1.4. Ethonium Ion (C₂H₇⁺) and Analogs. The next higher alkonium ion, the ethonium ion (protonated ethane, C₂H₇⁺) 449a and 449b (Scheme 3.15), is analogous to its parent CH₅⁺ ion. Protonation of ethane can take place either at a C–H bond or at the C–C bond, but the interconversion of the resulting ions is a facile low-energy process. Experimental studies by Hirooka and Kebarle (pulsed electron beam MS)⁷⁴⁸ and later by Lee et al. (IR spectroscopy)⁸²¹ have shown the existence of isomeric C₂H₇⁺ cations in the gas phase with an energy difference of 7–8 kcal mol⁻¹. The 449b C–C protonated form is preferred over the 449a C–H protonated form by
about 4.4 kcal mol$^{-1}$ (ab initio calculations). Such a protonation process would be consistent with the observed H–D exchange in labeled systems as well as with the formation of methane as a byproduct in the protolytic cleavage of ethane in superacids. FT–ICR MS experiments showed that intramolecular hydrogen randomization is a very fast process in the gas-phase preceding the decomposition or any other transformations of C$_2$H$_7^+$. Subsequent theoretical investigations, however, indicated that a third isomer also exists. This may be considered to be an ethyl cation solvated by H$_2$ or a complex between bridged protonated ethylene and a hydrogen molecule. Recent FT–ICR experiments for the reaction of CH$_3^+$ and CH$_4$ leading to the intermediacy of the C$_2$H$_7^+$ ion lent support to the existence of structure 450, which is lower in energy than structure 449. It was also suggested that the isomer of higher energy identified in previous experiments as structure 449 may, in fact, correspond to structure 450. Interestingly, Hiraoka and Kebarle also considered but discounted the possibility of complexes between C$_2$H$_5^+$ and H$_2$.

Various transformations of ethane on zeolites were also interpreted by invoking the involvement of protonated ethane. The hydrogen exchange has been studied using local density calculations (DFT with double-$\xi$ plus polarization basis set), applying the B3LYP and MP2 methods (6-31G** basis set) or using DFT and an analysis with the atoms-in-molecules method. The T3 zeolite cluster model (a cluster formed by three tetrahedral units) is generally used in most theoretical works. Structure 451 is suggested to be the transition state of hydrogen exchange characterized by a slightly ionic interaction between a distorted C$_2$H$_7^+$ structure and a negatively charged zeolite cluster.

The preferred structure of the diprotonated C$_2$H$_8^{2+}$ ethane dication (452) considered theoretically incorporates two pentacoordinate carbons and an unprotonated C–C bond (HF/6-31G* level). A new calculation by Olah et al. (MP2/6-31G**) has
shown that both the $C_2$ symmetry structure $452$ and the $C_{2v}$ symmetry structure $453$ are the minima on the potential energy surface, with $453$ being more stable by 0.4 kcal mol$^{-1}$ than $452$.

Schmidbaur and co-workers$^{829}$ have prepared and characterized the tetraaurated ethonium cations $454$. The MeC(AuP)$_4$ unit has a square-pyramidal geometry with the methyl group in apical position. The bonding interactions between neighboring Au atoms indicated by the short Au–Au distances (2.8 Å average) along the edges strongly contribute to stability.

3.5.1.5. Proponium Ions and Analogs. The higher alkonium ions, including protonated propane (C$_3$H$_9^+$), have been observed in the gas phase by high-pressure mass spectrometry.$^{746,748,749}$ In solution, the higher hydrocarbons show an increasing tendency to form C–H–C three-center, two-electron bonds on protonation as evidenced by the increasing tendency to form C–C bond cleavage products.

Hiraoka and Kebarle$^{748,830}$ studied the C$_3$H$_9^+$ protonated propane cation in the gas phase and found two isomers (cations $455$ and $456$). The C-protonated cation $455$ was shown to be of lower energy and also much more stable toward dissociation to C$_2$H$_5^+$ + CH$_4$ or sec-C$_3$H$_7^+$ + H$_2$ than the 2-H-protonated (456) cation. The energy barrier of the interconversion of the ions was calculated to be 9.1 kcal mol$^{-1}$.

Two isomeric proponium ions, cation $455$ and $457$ were computed by Collins and O’Malley$^{831}$ (DFT and MP2 calculations). The 2-H-protonated cation $456$, in turn, was suggested to be rather the transition state for the interconversion of the ions. Structure $456$ is better described as the van der Waals complex of sec-C$_3$H$_7^+$ and H$_2$, which was already suggested by Hiraoka and Kebarle.$^{748}$ Mota and co-workers$^{832}$ have recently
calculated the potential energy surface of the \( \text{C}_3\text{H}_9^+ \) cation [MP4(SDTQ)/6-311++G**/MP2(full)/6-31G** level]. In accordance with previous results, the C-proponium cation (455) was found to be of lowest energy, but the complex sec-C\( _3\text{H}_7^+ + \text{H}_2 \) lies only 0.3 kcal mol\(^{-1}\) above structure 455. The C–H bond lengths in the 3e–2e interactions are 1.272 and 1.188 Å, whereas the C–C bond distance is 2.099 Å. The interconversion between the 1-H-protonated cation (457) and the C-proponium cation (455) was shown to have no energy barrier. This result has relevance to zeolite chemistry. On zeolites where steric effects are important, the primary—that is, more accessible—hydrogens are protonated initially to yield the 1-H-proponium cation (457) (kinetic control), which then easily rearranges to give the thermodynamically more stable C-proponium ion.

On the potential energy surface of diprotonated propane (\( \text{C}_3\text{H}_{10}^{2+} \)), three structures were located as minima (MP2/6-31G** level).\(^{788}\) The 1-H,2-H-diprotonated and 1-H,3-H-diprotonated forms (458 and 459) are of \( \text{C}_1 \) and \( \text{C}_2 \), symmetry, respectively, whereas the 1-H,C-diprotonated structure (460) has \( \text{C}_1 \) symmetry. Structure 459, a distonic dication with the two charge-bearing centers separated by one carbon, is significantly more stable (by 22.6 kcal mol\(^{-1}\)) than structure 458 (a gitonic dication with adjacent charges) and also more stable than structure 460 (by 6.9 kcal mol\(^{-1}\)).

3.5.1.6. Higher Alkoniun Ions. The acid-induced H–D exchange of isobutane (461) at conventional acidities (e.g., with deuteriosulfuric acid) was studied by Otvos and co-workers.\(^{833}\) All nine methyl hydrogens are readily exchanged, but not the methine hydrogen. The mechanistic explanation for this observation must involve formation of trivalent tert-butyl cation (1), probably in an oxidative ionization step (Scheme 3.16). The tert-butyl cation then undergoes reversible deuteration.

\[ \text{CH}_3\text{C}^+ - \text{D}_2\text{SO}_4 \rightarrow \text{(CH}_3\text{)}_3^+ \text{C}^+ \rightarrow \text{H}_3\text{C} \text{C}_{\text{CH}_3} \]

Scheme 3.16
involving isobutylene, with the process repeating itself and thus accounting for exchange of the methyl hydrogens with deuteriated sulfuric acid.

The tert-butyl cation (1) reforms isobutane via hydride abstraction from isobutane according to Bartlett et al., Nenitzescu et al., and Schmerling involving the tertiary C–H bond only through intermediate structure 463, and thus not exchanging the methine hydrogen.

\[
\text{(CH}_3\text{)}_2\text{C} + \text{D}^+ \rightarrow \text{(CH}_3\text{)}_2\text{C} \quad \text{H} \quad \text{D}^+ \rightarrow \text{(CH}_3\text{)}_2\text{CD} \quad (3.123)
\]

In contrast, Olah et al. showed that in deuteriated superacidic media (e.g., DSO\textsubscript{3}F–SbF\textsubscript{5} or DF–SbF\textsubscript{5} at low temperatures), initially only the methine hydrogen is exchanged (with the acid), indicating no deprotonation–protonation equilibria involving species such as 1 and 462. The latter reaction proceeds through the intermediary of the 464 arising by protonation (deuteriation) of the tertiary C–H bond of isobutane [Eq. (3.123)]. Subsequent reactions exchange the methyl hydrogens through protonation (deuteriation) of the methyl groups.

Similar regioselectivity of exchange was found in triflic acid. Moreover, a fast deuterium exchange at all C–H bonds was observed in isobutane recovered after short contact times with DF–SbF\textsubscript{5} at 0°C (in contrast to −78°C). Isomeric carbonium ions 465\textsubscript{a}, 465\textsubscript{b}, and 465\textsubscript{c} are formed in equilibrium. The relative concentration of these pentacoordinate reaction intermediates, in accord with the Olah σ-basicty concept, depends only on the relative basicity of the proton-accepting bonds. An extended study with various C\textsubscript{3}–C\textsubscript{5} alkanes resulted in similar observations. The amount of hydrogen formed up to about 20 mol% of SbF\textsubscript{5} roughly parallels conversion, in agreement with the protolytic ionization.

\[
\begin{align*}
\text{D}^+ & \rightarrow \text{H} \\
\text{H}_2\text{C} \quad \text{CH}_3 \quad \text{C} \quad \text{H} \\
\text{CH}_3 & \quad \text{C} \quad \text{H} \\
\text{H}_3\text{C} & \quad \text{CH}_3 \\
\end{align*}
\]

Evidence for a C–C protonated C\textsubscript{4}H\textsubscript{11}\textsuperscript{+} ion (466) resembling cation 463 was obtained by Siskin. When studying the HF–TaF\textsubscript{5}-catalyzed ethylation of a large
excess of ethane with ethylene in a flow system, \( n \)-butane (467) was obtained as the only four-carbon product free from isobutane [Eq. (3.124)]. This remarkable result can only be explained by C–H bond ethylation of ethane, through the five-coordinate carbocation intermediate 466 which subsequently yields \( n \)-butane (467) by proton elimination. Use of a flow system that limits the contact of the product \( n \)-butane with the acid catalyst is essential, because on more prolonged contact, isomerization of \( n \)-butane to isobutane occurs.

\[
\text{CH}_3\text{CH}_3 + [\text{CH}_3\text{CH}_2]^+ \rightleftharpoons \begin{array}{c}

\text{467}
\end{array}
\]

(3.124)

Alternatively, if the reaction involved trivalent \( n \)-butyl cation 468 (from ethylation of ethylene) the ion would inevitably rearrange via 1,2-hydrogen shift to sec-butyl cation 19, which in turn would isomerize into the tert-butyl cation (1) and thus give isobutane (461) [Eq. (3.125)].

\[
\text{H}_2\text{C}=\text{CH}_2 + [\text{CH}_3\text{CH}_2]^+ \rightleftharpoons [\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_3]^+ \xrightarrow{1,2-\text{H}} \begin{array}{c}
\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_3 \\
\text{468}
\end{array} \xrightarrow{+} \begin{array}{c}
\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_3 \\
\text{468}
\end{array} \leftarrow \begin{array}{c}
\text{(CH}_3\text{)}_2\text{C}^+ \\
\text{19}
\end{array} \xrightarrow{+} \begin{array}{c}
\text{(CH}_3\text{)}_2\text{CH} \\
\text{461}
\end{array}
\]

(3.125)

The pulsed electron beam MS technique was also used by Hiraoka and Kebarle\(^{842}\) to study the \( C_4H_{11}^+ \) cations. In the ion–molecule reaction of ethane and the ethyl cation, two species were observed and identified as the 2-\( H \)-\( n \)-butonium cation 469 and the 2-\( C \)-\( n \)-butonium cation 470. C–C protonated ion 470 formed first rearranges to C–H protonated ion 469 (energy barrier = 9.6 kcal mol\(^{-1}\)) and then dissociation to sec-C\( _4\)H\(_9^+ \) + H\(_2\) takes place.

Three cations, an \( H \)-protonated (471) and two C-protonated (470 and 472) isomers were found by Collins and O’Malley\(^{831}\) by DFT and MP2 calculations. Ion 472 is more stable than ion 470 by about 5 kcal mol\(^{-1}\). Eleven stable isomeric protonated butane cations including rotamers were found by extensive studies by Mota and co-workers\(^{843}\) [MP4SDTQ(fc)/6-311++G***/MP2(full)6-31G** level]. The stability order 2-\( C \)-\( n \)-butonium (470) > 1-\( C \)-\( n \)-butonium (472) > 2-\( H \)-\( n \)-butonium (469) > 1-\( H \)-\( n \)-butonium (471) was interpreted in terms of charge delocalization in the involved 3\( c \)--2\( e \) bonds. Cation 471 prefers to rearrange to cation 472, whereas cation...
decomposes to \( \text{sec-C}_4\text{H}_9^+ + \text{H}_2 \). Both cations 471 and 472 are higher in energy than the corresponding van der Waals complexes (\( \text{C}_2\text{H}_5^+ + \text{C}_2\text{H}_6 \), \( \text{sec-C}_4\text{H}_9^+ + \text{H}_2 \), and \( \text{n-C}_3\text{H}_7^+ + \text{CH}_4 \)). Good agreement was found between experimental and computed proton affinity values (153.7 kcal mol\(^{-1}\) versus 156.7 kcal mol\(^{-1}\)). An exploratory topological study of the Laplacian of the electronic charge density by Jubert and co-workers\(^{844}\) was performed on the 11 butonium carbocations.

Geometries and energies of the conformers of the symmetrically protonated \( \text{C}_4\text{H}_{11}^+ \) cation 470 have recently been studied by \textit{ab initio} methods.\(^{845}\) The \textit{trans}-\( \text{C}_4\text{H}_{11}^+ \) and the \textit{gauche} rotamer with a staggered dihedral for the bridging proton are of the lowest energy, but all conformers lie within a 1-kcal mol\(^{-1}\) range. The best method [CCS(T)/cc-pVTZ] used for optimization of the geometry of the \( C_2 \)-symmetry minimum for \textit{trans}-\( \text{C}_4\text{H}_{11}^+ \) gave the following bond geometry values: \( \text{C}--\text{H} \) bond length = 1.2424 Å, \( \text{C}--\text{C} \) bond distance = 2.177 Å, \( \text{C}--\text{H/CH}_3 \) bond angle = 122.4°.

The reaction of the isopropyl cation with methane to give the isobutonium ion was also studied by Hiraoka and Kebarle.\(^{748}\) The \( C \)-protonated cation 473 has a heat of formation of 170.7 kcal mol\(^{-1}\). Mota et al.\(^{846}\) have characterized by \textit{ab initio} studies [MP2(full)/6-31G** level] three structures (473–475) and two van der Waals complexes with increasing energies in the order 473 < 474 < 475. The \( \text{C}--\text{H} \) bond lengths in the 3c–2e interactions are 1.470 and 1.137 Å, whereas the \( \text{C}--\text{C} \) bond distance is 2.470 Å. Decomposition of the cations into the corresponding van der Waals complexes (474 to \( \text{sec-C}_3\text{H}_7^+ + \text{CH}_4 \) and 475 to \( \text{tert-C}_4\text{H}_9^+ + \text{H}_2 \)) was found to have low or no activation energy. This is due to the high stability of the carbenium ions they collapse to. Using DFT calculations, Collins and O’Malley have arrived at the same conclusion for both structure 473 and \( C--C \) protonated neopentane.\(^{831}\)

Seitz and East selected five isomeric protonated octane isomers (\( \text{C}_8\text{H}_{19}^+ \)), all featuring \( \text{C}--\text{H}--\text{C} \) or \( \text{C}--\text{H}--\text{H} \) 3c–2e bonds for their theoretical studies (\textit{ab initio} calculations at the MP2/6-31G(d) level of theory).\(^{847}\) In most cases, dissociation into ion–molecule complexes was found to be again barrierless. Proton affinities of \( \text{C}--\text{C} \) and \( \text{C}--\text{H} \) bonds are in the range 154–187 kcal mol\(^{-1}\) and 139–150 kcal mol\(^{-1}\), respectively.

There is a general pattern having emerged from the theoretical works performed for higher protonated alkanes.\(^{847}\) (i) Protonation of alkanes always produces a \( \text{C}--\text{H}--\text{C} \) or \( \text{C}--\text{H}--\text{H} \) 3c–2e bond through the attack of \( \text{C}--\text{C} \) or \( \text{C}--\text{H} \) bonds, respectively. (ii) The \( C \)-protonated structures are always lower in energy than the \( H \)-protonated structures with an equivalent carbon skeleton. (iii) Of the \( C \)-protonated structures, cations with more substituted carbon atoms participating in the 3c–2e bond have the higher stability.
Diprotonated \(n\)-butane and isobutane cations (\(\text{C}_4\text{H}_{12}^{2+}\)) have been computed by Olah et al.\(^7\) Two distonic dications [the 1-\(\text{H}\),4-\(\text{H}\)-diprotonated (476) and the terminal C–\(\text{H}\) and C–C diprotonated (477) forms] were found to have energy minima (MP2/6-31G** level), with structure 476 being more stable by only 1.3 kcal mol\(^{-1}\).

For diprotonated isobutane (\(\text{C}_4\text{H}_{12}^{2+}\)) the structures found as stable minima are analogous to those computed for diprotonated propane (\(\text{C}_3\text{H}_{10}^{2+}\)). Again, structure 478 (a distonic dication) is 17.7 kcal mol\(^{-1}\) more stable than structure 479 (a gitonic dication), whereas structure 480 is only slightly less stable than 478 (2.6 kcal mol\(^{-1}\)).\(^7\)

Olah, Prakash, and Rasul\(^1\) have recently reported the structure of the protonated tert-pentyl cation (\(\text{C}_5\text{H}_{12}^{2+}\), diprotonated isopentane dication). Of the five minima located on the potential energy surface, structure 481 was found to be the global minimum, being even more stable than the tert-pentyl cation (23 and 24). Structure 481 has a trivalent carbocationic center and a pentacoordinate carbonium ion center (involving a 3–2\(e\) bond) separated by a carbon atom. The ion can be considered a carbenium–carbonium dication. One of the hydrogens of each methyl group attached to the carbocationic center is aligned in plane with the empty \(p\) orbital. These bonds are elongated (1.11 Å and 1.12 Å) and the corresponding H–C–C angles are significantly smaller (101° and 102°) than the other bond angles (113°–116°), which indicates significant hyperconjugation from two C–\(\text{H}\) \(\sigma\) bonds. In other structures with higher energy, the positive charges are closer to each other, generating larger intramolecular coulombic repulsion.

Protonation of spiro[2.2]pentane 482 yields the \(\text{C}_5\text{H}_9^+\) ions. Cation 483 was shown to be the initial protonated spiropentane by early experimental (MS) and theoretical
(semiempirical) studies (Scheme 3.17). Once formed, cation 483 rearranges to pyramidal intermediate 484, which yields cyclopentyl cation 33 upon ring opening. A combination of experimental methods (nuclear decay, radiolysis, FT–ICR mass spectrometry) and *ab initio* calculations (HF/6-31G* and MP2/6-31G* levels) performed by Schleyer and co-workers\(^8\) showed that the corner-protonated cation 485 is a relatively long-lived intermediate in the gas-phase. Edge-protonated isomeric cation 486, in turn, is less stable than ion 485 by 35.5 kcal mol\(^{-1}\).

In a subsequent calculational study [HF and MP2 levels of theory with 6-31G(d) basis set and MP4(SDQ)], Szabó and Cremer\(^8\) explored the C\(_7\)H\(_{11}\)\(^+\) potential energy surface. Cation 487 (tricyclo[4.1.0.0\(^1,3\)]heptyl cation), the protonated ethano-bridged derivative of spirocyclopentyl cation, was considered to be the missing link between the bicyclo[3.2.0]hept-3-yl cation 488 and the 7-norbornyl cation 489. It is a kinetically stabilized species separated from cations 488 and 489 by 18.9 and 15.9 kcal mol\(^{-1}\), respectively.

**3.5.1.7. Adamantionium Ions.** There exists a single theoretical study for adamantionium ions.\(^8\) Mota and co-workers have found three isomeric structures (490–492) and two van der Waals complexes (1-adamantyl cation + H\(_2\) and 2-adamantyl cation + H\(_2\)) [MP2(full)/6-31G** level]. The C–H bond lengths in the 3c–2e interactions in ion 490 are 1.276 and 1.266 Å and in ion 491 are 1.266 and 1.280 Å. The C-adamantionium ion (492) has nonequivalent C–H bond distances (1.191 and 1.294 Å) and the C–C bond distance is 2.348 Å. Interestingly, the 2-adamantyl cation + H\(_2\) complex shows a nonclassical bonding nature similar to the
2-norbornyl cation. Cation 492 is the most stable, but it is 9.30 kcal mol\(^{-1}\) less stable than the 1-adamantyl cation + H\(_2\) complex.

3.5.2. Equilibrating and Bridged Carbocations

Some carbocations, because of their flat potential energy surfaces, show great tendency to undergo fast degenerate rearrangements, through intermolecular hydrogen or alkyl shifts leading to the corresponding identical structures.\(^{17-19,851}\) The question arises whether these processes are true equilibria between the limiting trivalent carbocations (“classical ion intermediates”) separated by low-energy level transition states or whether they are hydrogen- or alkyl-bridged higher-coordinate (nonclassical) carbocations. Extensive discussion of the kinetic and stereochemical results in these systems has been made, and it is not considered to be within the scope of this chapter to recapitulate the arguments. The reader is referred to reviews\(^ {17-19,851}\) and the original literature.

3.5.2.1. Degenerate 1,2-Shifts in Carbocations. Many acyclic and monocyclic tertiary and secondary cations undergoing degenerate 1,2-hydrogen (and alkyl) shift give average proton and carbon absorptions in their NMR spectra, even at low temperatures. If the exchange rate process is rapid on the NMR time scale, single sharp resonances will appear for the exchanging nuclei at frequencies that are weighted averages of the frequencies being exchanged. It has been possible to freeze exchange processes in some equilibrating ions by observing \(^{13}\)C NMR spectra at low temperature (ca. \(-160^\circ\text{C}\)) at high magnetic field strength (to enhance signal separation). Typically, the barriers for such migrations range from 2.4 to 10 kcal mol\(^{-1}\). Another important technique that has been immensely useful is the low-temperature solid-state \(^{13}\)C NMR spectroscopy.

The sec-butyl cation (19) has been prepared from 2-chlorobutane in SbF\(_5\)–SO\(_2\)ClF at \(-100^\circ\text{C}\) in a vacuum line by Saunders and Hagen\(^ {852,853}\) with very little contamination from the tert-butyl cation (1) (Scheme 3.18). Even at \(-110^\circ\text{C}\), only two peaks from 2,3 and 1,4 protons are observed in the \(^1\)H NMR spectrum of 19 (at \(\delta_{^1\text{H}}\) 6.7 and 3.2). This is consistent with a sec-butyl cation averaged by very rapid 1,2-hydride shifts (\(\Delta G^0 \approx 6\) kcal mol\(^{-1}\)). Warming the sample from \(-110\) to \(-40^\circ\text{C}\) first causes line broadening and then coalescence of the two peaks, revealing a rearrangement process making all protons equal on the \(^1\)H NMR time scale (indicating the formation of 1). Line-shape analysis gave an activation barrier of 7.5 \(\pm 0.1\) kcal mol\(^{-1}\) for the process. This low barrier is not compatible with a mechanism involving primary cations as suggested for the corresponding rearrangement of the isopropyl cation. It appears
necessary to invoke protonated methylocyclopropanes 493 as intermediates. The barrier for the irreversible rearrangement to 1 was measured to be about 18 kcal mol$^{-1}$, indicating that this rearrangement probably involves primary cationic structures as intermediates.

Olah and White$^{94}$ obtained an early $^{13}$C NMR INDO spectrum of 19 that showed a single peak from the two central carbon atoms in reasonable agreement with values calculated from model equilibrating ions. Therefore, it was concluded that 19 is a classical equilibrating ion rather than being bridged as in 494.

In a comprehensive $^{13}$C NMR spectroscopic study of alkyl cations, Olah and Donovan$^{95}$ applied the constancy of $^{13}$C methyl substituent effects to the study of equilibrating cations and their rearrangements. They calculated the chemical shifts of the 2-butyl cation (19) from both the isopropyl cation and tert-pentyl cation using methyl group substituent effects and reached practically the same result in both cases. The observed chemical shifts deviate from the calculated ones by 9.2 and 19.8 ppm for the equilibrating methyl and carbocation carbons, respectively. Therefore, a hydrogen-bridged intermediate (494) was suggested to be involved. A static hydrogen-bridged 2-butyl cation was excluded by the observation of two quartets in the fully $^1$H-coupled $^{13}$C NMR spectrum. Comparison with bridged halonium ions indicates that equilibrating hydrogen-bridged ions have more shielded carbons $[C(2), C(3)]$ than are observed experimentally for the 2-butyl cation. Therefore, it was suggested that the open-chain 2-butyl cation is of similar thermodynamic stability as the hydrogen-bridged 494 and that these intermediates in equilibrium may contribute to the observed average $^{13}$C NMR shifts. However, the percentage of different structures could not be calculated, owing to lack of accurate models to estimate $^{13}$C chemical shifts of hydrogen-bridged structures.

In a study of rates of degenerate 1,2-shifts in tertiary carbocations, Saunders and Kates$^{854}$ used higher-field (67.9 MHz) $^{13}$C NMR line broadening in the fast-exchange limit. The 2-butyl cation showed no broadening at $-140^\circ$C. Assuming the hypothetical “frozen out” chemical shift difference between C(2) and C(3) to be 227 ppm, an upper limit for $\Delta G^\ddagger$ was calculated to be 2.4 kcal mol$^{-1}$. 

---

[Scheme 3.18]
Application of the isotopic perturbation technique by Saunders et al.\textsuperscript{56} to the 2-butyl cation [Eq. (3.126)] showed it to be a mixture of equilibrating open-chain ions since a large splitting of the $^{13}$C resonance [C(2), C(3)] was obtained upon deuterium substitution.\textsuperscript{855}

\[
\begin{align*}
\text{D} & \rightarrow \text{D} \\
\text{D} & \rightarrow \text{D} \\
\end{align*}
\] (3.126)

The cross-polarization, magic-angle spinning method (CP MAS) has been applied by Myhre and Yannoni\textsuperscript{50} to cation 19 in the solid state at very low temperatures using $^{13}$C NMR spectroscopy. In the initial study, no convincing evidence for a frozen 2-butyl cation was obtained even at $-190^\circ$C. However, subsequently they managed to freeze out the equilibration of the 2-butyl cation (19) at $-223^\circ$C.\textsuperscript{62} It behaves like a normal secondary trivalent carbocation.

As mentioned earlier (Section 3.4.2), the cyclopentyl cation 33 shows a single peak in the $^1$H NMR spectrum of $^\delta^1$H 4.75 even at $-150^\circ$C.\textsuperscript{143} In the $^{13}$C NMR spectrum,\textsuperscript{856} a 10-line multiplet centered around 95.4 ppm with $J_{C-H} = 28.5$ Hz was observed. This is in excellent agreement with values calculated for simple alkyl cations and cyclopentane and supports the complete hydrogen equilibration by rapid 1,2-shifts [Eq. (3.127)].

\[
\begin{align*}
\text{etc.} \\
\end{align*}
\] (3.127)

Subsequently, Yannoni and co-workers\textsuperscript{857} succeeded in freezing out the degenerate hydride shift in 33 in the solid state at $-203^\circ$C. The observed $^{13}$C chemical shifts at $^\delta^{13}$C 320.0, 71.0, and 28.0 indicate the regular trivalent nature of the ion and are in good agreement with the estimated shifts in solution based on the average shift data.

The NMR spectrum of 2,2,3-trimethyl-2-butyl cation (tripptyl cation, 495) [Eq. (3.128)] consists of a single proton signal at $^\delta^1$H 2.90 for all the methyl groups.\textsuperscript{134} This indicates that all five methyl groups undergo rapid interchange through 1,2-methyl shifts. The chemical shift of the singlet methyl is similar to that of 2,3-dimethyl-2-butyl cation 496 [Eq. (3.129)], another equilibrating ion that undergoes rapid 1,2-hydride shifts.\textsuperscript{134}

\[
\begin{align*}
\text{etc.} \\
\end{align*}
\] (3.128)

\[
\begin{align*}
\text{etc.} \\
\end{align*}
\] (3.129)

The $^{13}$C NMR spectroscopic data of the average cationic center in 495 and 496 were found to be at $^\delta^{13}$C 205 and 197 ($J_{C-H} \approx 65$ Hz), respectively, indicating their regular trivalent carbenium nature. From studies of methyl substituents effects, Olah and Donovan\textsuperscript{95} reached the same conclusions and these are supported by laser Raman and
ESCA studies.\(^{72,858}\) Saunders and Vogel\(^{58}\) have introduced deuteriums into a methyl group of \(\text{495}\) (cation \(\text{497}\)) and thereby perturbed the statistical distribution of the otherwise degenerate methyl groups and split the singlet into a doublet. The \(\text{CD}_3\) group prefers to be attached to the tertiary carbon (\(\text{498}\)) [Eq. (3.130)].

\[
\begin{align*}
\text{D}_2\text{C} \quad & \quad \text{D}_2\text{C} \\
\text{497} \quad & \quad \text{498}
\end{align*}
\]

Saunders and Kates\(^{854}\) have been successful in measuring the rates of degenerate 1,2-hydride and 1,2-methide shifts of simple tertiary alkyl cations employing higher-field (67.9 MHz) \(^{13}\)C NMR spectroscopy. From line broadening in the fast-exchange limit, the free energies of activation (\(\Delta G^\ddagger\)) were determined to be 3.5 ± 0.1 kcal mol\(^{-1}\) at \(-136^\circ\text{C}\) for \(\text{495}\) and 3.1 ± 0.1 kcal mol\(^{-1}\) at \(-138^\circ\text{C}\) for \(\text{496}\). The rapid equilibrium in cations \(\text{495}\) and \(\text{496}\) has been frozen out in the solid state at \(-165^\circ\text{C}\) and \(-160^\circ\text{C}\), respectively, by Yannoni and co-workers.\(^{857}\)

Many more cyclic and polycyclic equilibrating carbocations have been reported. Some representative examples, namely, the bisadamantyl (\(\text{499}\)),\(^{859}\) 2-norbornyl (\(\text{500}\)),\(^{40}\) 7-perhydropentalenyl (\(\text{501}\)),\(^{188}\) 9-decalyl (\(\text{502}\)),\(^{188}\) and pentacyclopropylethyl (\(\text{503}\))\(^{860}\) cations, are given in Scheme 3.19. All these systems again involve hypercoordinate high-lying intermediates or transition states.

\[

\text{503}
\end{align*}
\]

Scheme 3.19
3.5.2.2. The 2-Norbornyl Cation. The 2-norbornyl cation (C$_7$H$_{11}$$^+$) holds a unique position in the history of organic chemistry because of the important role it has played in the bonding theory of carbon compounds. Since Winstein’s early solvolytic work in 1949 the 2-norbornyl cation was at the heart of the so-called nonclassical ion problem, and no other system has been studied so much by various physical and chemical methods and by so many investigators. The controversy about it is well known, and the question has been whether the ion has a symmetrically bridged nonclassical structure 504 with a pentacoordinate carbon atom or is a rapidly equilibrating pair of classical trivalent ions 505a and 505b.

![Diagram of 504 and 505](image)

This controversy has been instrumental in the development of important structural methods in physical organic chemistry with respect to critical evaluation of results as well as to concepts behind the methods.

The methods that were developed in the early 1960s to generate and observe stable carbocations in low-nucleophilicity solutions were successfully applied to direct observation of the norbornyl cation (C$_7$H$_{11}$$^+$). Preparation of the ion by the “σ route” from 2-norbornyl halides, by the “π route” from 4-(2-haloethyl)-cyclopentenes, and by the protonation of nortricyclene (“bent σ route”) all led to the same 2-norbornyl cation.

The method of choice for the preparation of the norbornyl cation (giving the best-resolved NMR spectra, free of dinorbornylhalonium ion equilibration) is from exo-2-fluoronorbornane in SbF$_5$–SO$_2$ (or SO$_2$ClF) solution (Scheme 3.20).

![Scheme 3.20](image)

In a joint effort, Saunders, Schleyer, and Olah first investigated the 60-MHz $^1$H NMR spectrum of the 2-norbornyl cation in the early 1960s. Subsequently, Olah and co-workers carried out detailed 100-MHz $^1$H and 25-MHz $^{13}$C NMR spectroscopic studies in the early 1970s at successively lower temperatures. From the detailed $^1$H NMR investigations at various temperatures (RT to $-154^\circ$C), the barrier for the
2,3-hydrogen shift, as well as the 6,1,2-hydrogen shift, was determined by line-shape analysis and found to be $10.8 \pm 0.6 \text{kcal mol}^{-1}$ and $5.9 \text{kcal} \pm 0.2 \text{ mol}^{-1}$, respectively (Figure 3.19).\textsuperscript{38}

The 60-MHz $^1\text{H}$ NMR spectrum of the 2-norbornyl cation at room temperature shows a single peak at $\delta^{1}\text{H} 3.10$ for all protons, indicating fast 2,3-hydrogen, 6,1,2-hydrogen, and Wagner–Meerwein shifts.\textsuperscript{867} Cooling the solution of the 2-norbornyl cation in the SbF$_5$–SO$_2$ClF–SO$_2$F$_2$ solvent system down to $-100^\circ\text{C}$ at 395 MHz (Figure 3.20) results in three peaks at $\delta^{1}\text{H} 4.92$ (4 protons), 2.82 (1 proton), and 1.93 (6 protons), indicating that the 2,3-hydrogen shift is fully frozen, whereas the 6,1,2-hydrogen and Wagner–Meerwein shifts are still fast on the NMR time scale.\textsuperscript{868}

Cooling the solution down further to $-158^\circ\text{C}$ results in significant changes in the spectrum. The peak at $\delta^{1}\text{H} 4.92$ splits into two peaks at $\delta^{1}\text{H} 6.75$ and 3.17 with a ratio of 2:2. The high-field peak broadens and splits into two peaks at $\delta^{1}\text{H} 2.13$ and 1.37 and in the ratio 4:2. The peak at $\delta^{1}\text{H} 2.82$ remains unchanged. The line width ($\sim 60\text{ Hz}$) observed at 395 MHz was found to be rather small as compared to the one obtained\textsuperscript{868} at 100 MHz ($\sim 30\text{ Hz}$). This has some implications. If the line width were due to any slow exchange process occurring at this temperature, the line width should have broadened 15.6 times at 395 MHz over the one observed at 100 MHz. The observation of comparably narrow line widths at 395 MHz indicates that either the 6,1,2-hydrogen shift and the Wagner–Meerwein shift (σ-bond shift) are completely frozen and the 2-norbornyl cation has the symmetrically bridged structure \textbf{504} or the 6,1,2-hydrogen

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure36.png}
\caption{Degenerate shifts in the 2-norbornyl cation (one of the carbons is labeled for clarity).}
\end{figure}
The shift is frozen and the so-called Wagner–Meerwein shift (if any) is still fast on the NMR time scale through a very shallow activation energy barrier (less than 3 kcal mol\(^{-1}\)). The second possibility raises the question as to the nature of the ion still undergoing equilibration through an extremely low-activation energy barrier. It has been pointed out\(^{33}\) that if such a process occurs, it must be exclusively between unsymmetrically bridged ions 506 equilibrating through the intermediacy of the symmetrically bridged species 504.

Figure 3.20. 395-MHz \(^1\)H NMR spectra of 2-norbornyl cation in SbF\(_5\)–SO\(_2\)ClF–SO\(_2\) solution.
The unsymmetrically bridged ions 506 would be indistinguishable from the symmetrically bridged system 504 in solution NMR experiments. (However, see subsequent discussion of solid-state low-temperature $^{13}$C NMR as well as ESCA studies.) It is important to recognize that equilibrating open classical cations 505 cannot explain the NMR data and thus cannot be involved as populated species.

The 50-MHz $^{13}$C NMR spectrum of the 2-norbornyl cation (C$_{7}$H$_{11}$)$^{+}$ has also been obtained in the mixed SbF$_{5}$–SO$_{2}$ClF–SO$_{2}$F$_{2}$ solvent system at $-159^\circ$C. To obtain a well-resolved $^{13}$C NMR spectrum, the cation was generated from 15% $^{13}$C-enriched exo-2-chloronorbornane [the label corresponds to one carbon per molecule randomly distributed over the C(1), C(2), and C(6) centers]. The ionization of the $^{13}$C-enriched exo-2-chloronorbornane in SbF$_{5}$–SO$_{2}$ClF–SO$_{2}$F$_{2}$ solution at $-78^\circ$C results in the 2-norbornyl cation wherein the $^{13}$C label is distributed evenly over all the seven carbons as a result of slow 2,3-hydrogen and fast 6,1,2-hydrogen and Wagner–Meerwein shifts.

At $-80^\circ$C, the 50-MHz $^{13}$C NMR spectrum of the cation (Figure 3.21) showed three absorptions at $\delta$ H 91.7 (quintet, $J_{C-H} = 55.1$ Hz), 37.7 (doublet, $J_{C-H} = 153.1$ Hz),

![Figure 3.21. 50-MHz $^{13}$C NMR spectra of the 2-norbornyl cation in SbF$_{5}$–SO$_{2}$ClF–SO$_{2}$F$_{2}$ solution.](image-url)
and 30.8 (triplet, $J_{\text{C-H}} = 139.1$ Hz), indicating that the 2,3-hydrogen shift is frozen, but the 6,1,2-hydrogen and the Wagner–Meerwein shift is still fast on the NMR time scale. Cooling the solution down results in broadening and slow merger into the baseline of the peaks at $\delta^{13}\text{C}$ 91.7 and 30.8, but the peak at $\delta^{13}\text{C}$ 37.7 remains relatively sharp. At $-159^\circ\text{C}$, the peaks at $\delta^{13}\text{C}$ 91.7 and 30.8 separate into two sets of two peaks at $\delta^{13}\text{C}$ 124.5 (doublet, $J_{\text{C-H}} = 187.7$ Hz), 21.2 (triplet, $J_{\text{C-H}} = 147.1$ Hz), and 36.3 (triplet, $J_{\text{C-H}} = 131.2$ Hz), 20.4 (triplet, $J_{\text{C-H}} = 153.2$ Hz), respectively. The observed $^{13}\text{C}$ NMR spectral data at $-159^\circ\text{C}$ complement well the 395 MHz $^1\text{H}$ NMR data at $-158^\circ\text{C}$. The observation of the C(1) and C(2) carbons at $\delta^{13}\text{C}$ 124.5 and the C(6) carbon at $\delta^{13}\text{C}$ 21.2 clearly supports the bridged structure for the ion. Five (or higher) coordinate carbons generally show shielded (upfield) $^{13}\text{C}$ NMR shifts.

Applying the additivity of chemical shift analysis\(^{55}\) to the 2-norbornyl cation also supports the bridged nature of the ion. A chemical shift difference of 168 ppm is observed between the ion (C$_7$H$_{11}^+$) and its parent hydrocarbon [i.e., norbornane (507)], whereas ordinary trivalent carbocations such as the cyclopentyl cation (33) reveal a chemical shift difference of $\sim$360 ppm.\(^{55}\)

![Diagram](image)

Yannoni, Macho, and Myhre\(^{869}\) obtained magic-angle spinning cross-polarization $^{13}\text{C}$ NMR spectra of the $^{13}\text{C}$-enriched 2-norbornyl cation in SbF$_5$ solid matrix down to $-196^\circ\text{C}$. The solid-state chemical shifts and measured barriers for the 6,1,2-hydrogen shift of 6.1 kcal mol$^{-1}$ correlate well with the discussed solution data. Subsequently, they even obtained $^{13}\text{C}$ NMR spectra in the solid state at $-268^\circ\text{C}$ (5 K),\(^{870}\) a remarkable achievement indeed.

A fortuitous combination of large isotropic chemical shifts and small chemical shift anisotropies permitted them to obtain reasonable resolution of the positively charged carbon resonance without the need for magic-angle spinning. Comparison with their previous MAS spectra\(^{869}\) down to $-196^\circ\text{C}$ shows that the nonspinning spectra reflect slowing of 6,2,1-hydride shift. Since no changes were observed in the positively charged carbon resonance (at $\delta^{13}\text{C} \sim 125$) between $-173^\circ\text{C}$ and $-268^\circ\text{C}$ (Figure 3.22), the authors concluded\(^{870}\) that if the hypothetical 1,2-Wagner–Meerwein shift is still occurring, then it should be rapid, and an upper limit for the barrier for such a process (involving structures 505) can be estimated to be no greater than 0.2 kcal mol$^{-1}$. This can be taken as the most definitive evidence besides ESCA studies for the symmetrical $\sigma$-bridged structure of the 2-norbornyl cation. Subsequently, Dewar and Merz\(^{871}\) raised the possibility of low-energy carbon tunneling between unsymmetrically delocalized nonclassical ions such as 506 based on MINDO/3 calculations. Such carbon tunneling, however, is unlikely.
As discussed earlier, the method of observing changes in NMR spectra produced by asymmetric introduction of isotopes (isotopic perturbation) as a means of distinguishing systems involving equilibrating species passing rapidly over a low barrier from molecules with single-energy minima, intermediate between the presumed equilibrating structures, has been developed by Saunders et al.\textsuperscript{56} Applying this method to the 2-norbornyl cation further supports its bridged nature.\textsuperscript{872} In the $^{13}$C NMR spectrum of the 2-norbornyl cation, even at low temperatures, besides Wagner–Meerwein rearrangement, the 6,1,2-hydrogen shift has a barrier of only 5.9 kcal mol$^{-1}$ and results in a certain amount of line broadening of the lowest field signal observed. Even in the ion with no deuterium, the downfield signal at $\delta^{13}$C $\sim$ 124.5 [C(2) and C(6) cyclopropane-like carbons] is found to be 2 ppm wide. Nevertheless, no additional isotopic splitting or broadening was observed with either 2-monodeutero or 3,3-dideutero cations, and therefore the isotopic splitting can be no more than 2 ppm. This is true even if a slow 6,2-hydride shift converts part of the latter ions to a symmetrical 5,5-dideutero system that lacks an equilibrium isotope effect. This result, when compared with the significantly larger splitting observed for deuteriated dimethylcyclopentyl (508) and dimethylnorbornyl (509) cations\textsuperscript{61,872} (known to be equilibrating ions) is in accordance with the nonclassical nature of the 2-norbornyl cation. A similar

\]

Farnum and Olah’s groups, respectively, have extended the so-called Gassman–Fentiman tool of increasing electron demand coupled with \(^1\)H and \(^{13}\)C NMR spectroscopy as the structural probe under stable ion conditions to show the onset of \(\pi\), \(\pi\sigma\), and \(\sigma\) delocalization in a variety of systems.\(^{153,154,873–883}\) The \(^{13}\)C NMR chemical shifts of the cationic carbon of a series of regular trivalent 1-aryl-1-cyclopentyl, 1-aryl-1-cyclohexyl, 2-aryl-2-adamantyl, 6-aryl-6-bicyclo[3.2.1]octyl, and 7-aryl-7-norbornyl cations (so-called classical cations) correlate linearly with the observed cationic chemical shifts of substituted cumyl cations over a range of substituents \(^{881–883}\) [generally from the most electron-releasing 4-MeO to the most electron-withdrawing 3,5-(CF\(_3\))\(_2\) groups].

However, 2-aryl-2-norbornyl cations \(510\) show deviations from linearity in such chemical shift plots with electron-withdrawing substituents indicative of the onset of nonclassical \(\sigma\)-delocalization fully supporting the nonclassical nature of the parent secondary cation (Figure 3.23). These conclusions were criticized by Brown et al.\(^{883}\) In a subsequent paper, Olah et al.\(^{67}\) have shown major flaws in such criticisms.

As mentioned earlier, since in electron spectroscopy the time scale of the ionization processes is on the order of \(10^{-16}\) s, definite ionic species are characterized, regardless of their possible intra- and intermolecular rearrangements (e.g., Wagner–Meerwein rearrangements, hydride shifts, etc.) even at rates equaling or exceeding those of vibrational transitions. Thus, electron spectroscopy can give an unequivocal answer to the long-debated question of the “classical” or “nonclassical” nature of the norbornyl cation, regardless of the rate of any possible equilibration processes.

Olah et al.\(^{39}\) succeeded in observing the ESCA spectrum of the norbornyl cation \(504\) and compared it with those of the 2-methyl-2-norbornyl cation \(511\) and other trivalent carbenium ions such as the tert-butyl \(1\), cyclopentyl \(33\), and 1-methylcyclopent-1-yl \(28\) cations. The 1s electron spectrum of the norbornyl cation shows no high-binding energy carbenium center, and a maximum separation of less than 1.5 eV is observed between the two “cyclopropyl”-type carbons, to which bridging takes place from the other carbon atoms (including the pentacoordinate bridging carbon). In contrast, the 2-methyl-2-norbornyl cation \(511\) shows a high-binding energy carbenium center, deshielded with the \(\Delta E_b\) of 3.7 eV from the other carbon atoms. Typical ESCA shift differences are summarized in Table 3.6.
Figure 3.23. Plot of the $^{13}$C NMR chemical shifts of the cationic center of 2-aryl-2-norbornyl cations versus those of model 1-aryl-1-cyclopentyl cations.

Subsequently, Grunthaner reexamined the ESCA spectrum of the 2-norbornyl cation on a higher-resolution X-ray photoelectron spectrometer using highly efficient vacuum techniques. The spectrum closely matches the previously published spectra. Furthermore, the reported ESCA spectral results are consistent with the theoretical studies of Allen and co-workers on the classical and nonclassical norbornyl cation at the STO-3G and STO-4.31G levels. Using the parameters obtained by Allen and co-workers, Clark and co-workers were able to carry out a detailed interpretation of the experimental ESCA data for the core-hole state spectra at SCF STO-4.31G level and calculated equivalent cores at STO-3G level. Agreement between experimentally obtained spectra and those calculated for the nonclassical cation are good and dramatically different from those for the classical cation.

If the classical structure were correct, the 2-norbornyl cation would be a usual secondary carbocation with no additional stabilization provided by $\sigma$-delocalization (such as the cyclopentyl cation). The facts, however, seem to be to the contrary. Direct experimental evidence for the unusual stability of the secondary 2-norbornyl cation comes from the low-temperature solution calorimetric studies of Arnett and Petro. In a series of investigations, Arnett and Hofelich determined the heats of ionization ($\Delta H_i$) of secondary and tertiary chlorides in SbF$_5$–SO$_2$ClF [Eq. (3.131)] and subsequently alcohols in HSO$_3$F–SbF$_5$–SO$_2$ClF solutions [Eq. (3.132)].

\[
\begin{align*}
R-\text{Cl} + \text{SbF}_5 & \quad \overset{\Delta H_i}{\longrightarrow} \quad R^+\text{SbF}_5\text{Cl}^- \\
R-\text{OH} + \text{HSO}_3\text{F-SbF}_5 & \quad \overset{\Delta H_i}{\longrightarrow} \quad R^+\text{SbF}_5(\text{FSO}_3)^- + \text{H}_3\text{O}^+ 
\end{align*}
\]

However, it was found that whereas the difference observed in the heats of ionization of 2-methyl-2-exo-norbornyl chloride and 2-exo-norbornyl chloride in SbF$_5$–SO$_2$ClF solution is 7.4 kcal mol$^{-1}$, the same difference between the corresponding alcohols in HSO$_3$F–SbF$_5$–SO$_2$ClF solution is only 2.5 kcal mol$^{-1}$. This indicates that the heats of ionization values ($\Delta H_i$) seem to largely depend on the nature of the starting precursors (initial state effects). However, the observed differences are remarkably small for the corresponding secondary and tertiary cations, which generally is 10–15 kcal mol$^{-1}$. In the case of norbornyl, there seems to be at least 7.5 kcal mol$^{-1}$ extra stabilization. A further compelling evidence for the nonclassical stabilization of the 2-norbornyl cation also comes from Arnett’s measured heats of isomerization of secondary cations to tertiary cations. The measured heat of isomerization of 4-methyl-2-norbornyl cation 512 (secondary system) to 2-methyl-2-norbornyl cation 511 is $-6.6$ kcal mol$^{-1}$ [Eq. (3.133)]. In contrast, the related isomerization of sec-butyl cation 19 and tert-butyl cation 1 involved a difference in $\Delta H_i$ of $-14.2$ kcal mol$^{-1}$ [Eq. (3.134)].
Taking this latter value as characteristic of isomerization of secondary to tertiary ions, one must conclude that the secondary norbornyl ion $512$ has an extra stabilization of at least 7.6 kcal mol$^{-1}$. Fărcașiu$^{889}$ questioned these conclusions, arguing that they neglected to account for the extra stabilization by bridgehead methyl substitution as indicated by his molecular force field calculations. Schleyer and Chandrashekar$^{890}$ have subsequently pointed out that Fărcașiu failed to include corrections of β-alkyl branching. Correcting for this effect, there is still $6 \pm 1$ kcal mol$^{-1}$ extra stabilization in the 2-norbornyl cation for which no other reasonable explanation other than bridging was offered.

Gas-phase mass spectrometric studies$^{891–894}$ also indicate exceptional stability of the 2-norbornyl cation relative to other potentially related secondary cations. A study by Kebarle and co-workers$^{895}$ also suggests that the 2-norbornyl cation is more stable than the tert-butyl cation in the gas phase (based on hydride transfer equilibria from their respective hydrocarbons).

Subsequent experimental observations lent further strong support to the nonclassical structure of high stability. In 1987, Laube determined the crystal structure of the 1,2,4,7-anti-tetramethyl-2-norbornyl cation as the Sb$_2$F$_{11}$ salt$^{896}$ and redetermined the structure in 1994.$^{122,897}$ The geometry of the skeleton of the cation is significantly different than that of the norbornane skeleton and more similar to the geometry calculated for the symmetrical 2-norbornyl cation $504$. Forsyth and Panyachotipun$^{898}$ observed large isotope shifts for the $^{13}$C resonance at the cationic center of the deuteriated 2-methyl-2-norbornyl cation, which was attributed to the bridging structure. The IR spectra of the matrix-generated 2-norbornyl cation were recorded by Koch, Sunko and co-workers$^{899}$ at 150–200 K. The experimental and calculated spectra (MP2/6-31G* level)$^{899,900}$ computed on the 2-norbornyl cation of $C_s$ symmetry agree well and again support the bridged nonclassical structure. Finally, the stability of a range of bridgehead cations including the 2-norbornyl cation has been determined by the FT–ICR method on dissociative proton attachment of bromides and alcohols.$^{901}$ Good correlations were found for the stability of the ions with the solvolytic reactivity of bridgehead derivatives and theoretical calculations (MP2/6-311G** level) for hydride transfer of bridgehead hydrocarbons. The 2-norbornyl cation, a secondary carbocation, lies nicely on the correlation line of $\Delta G^0_{\text{exp}}$ versus $\Delta G^0_{\text{theor}}$, although this is defined by tertiary ions. The stability of the 2-norbornyl cation ($504$) is close to that of the 1-adamantyl cation, that is, $504$ is much more stable than simple classical secondary or strained tertiary cations. The calculated C–C bond lengths agree within 0.04 Å with that reported for $504$ in the gas phase and in solution by a high-level theoretical study.$^{902}$

Theoretical quantum mechanical calculations$^{903–908}$ have also been performed on the 2-norbornyl cation at various levels. These calculations reveal a significant preference for the $\sigma$-delocalized nonclassical structure. An extensive calculation by Schaefer and co-workers$^{906}$ using full geometry optimization for symmetrically and
unsymmetrically bridged systems showed a difference of only 1.0 kcal mol\(^{-1}\) between these structures. (Some confusion was introduced by Schaefer, who called the unsymmetrically bridged ion “classical.”) Similar high-level calculations, including electron correlations (with a double zeta plus polarization basis set), by Schleyer, Schaefer, and co-workers\(^\text{907}\) and Liu and co-workers,\(^\text{908}\) indicate that the only minimum on the 2-norbornyl cation potential energy surface is the symmetrically bridged structure. The nonclassical symmetrically bridged 2-norbornyl cation (504) was calculated to be 24.8 kcal mol\(^{-1}\) more stable than the isopropyl cation (based on the hydride transfer reaction). The structure with “classical” 2-norbornyl-like geometry (505), however, did not correspond to a fixed point on the potential energy surface. The extra stabilization of the bridged structure (504) was roughly estimated to be 12–15 kcal mol\(^{-1}\) at this high level of \textit{ab initio} theory.\(^\text{907,908}\)

In further theoretical studies, Schleyer and co-workers\(^\text{902,909}\) found that the nonclassical 2-norbornyl cation (504) is more stable than the classical structure 505, by 13.6 kcal mol\(^{-1}\). Cation 504 was shown to be the only stable form in the gas phase and in solution, and the classical form (505) is unlikely to be involved in solvolysis reactions [MP4(fc)SDQ/6-31G**/MP2(full)/6-31G*+ZPVE level]. A rigorous \textit{ab initio} calculation led to the suggestion that the classical 505 structure is an artifact and a transition state in the rearrangement of 504 into the bridged 2-norpinyl cation. The computed MP2-GIAO \(^{13}\)C chemical shifts for 504 are close to the experimental values, whereas those calculated by Schindler\(^\text{910}\) (IGLO) for 505 deviate considerably. The comparison of the chemical shifts for the two structures with the experimental data proves once again the symmetrical nonclassical structure.

Werstiuk and coworkers published a series of articles\(^\text{911–914}\) and showed that neither the 2-norbornyl cation nor the 1,2,4,7-\textit{anti}-tetramethyl-2-norbornyl cation is an energy minimum on the potential energy surface and they are not nonclassical, \(\sigma\)-bridged species [AIM (atoms in molecules) method]. In a recent extensive interpretation, Mamantov\(^\text{915}\) suggested a structure with H–C(1)–H \(\sigma\)-bond delocalization, that is, C(1) rather than C(6) being the hypercoordinated carbon atom. However, such a structure is highly unlikely based on the experimental results.

Nine nonclassical carbocations derived from cyclic hydrocarbons including the 2-norbornyl cation have recently been studied by means of \textit{ab initio} calculations (MP2/6-311G**).\(^\text{916}\) Electron density, chemical shifts, geometries, energetics and orbital interactions within the natural bond orbital (NBO) formalism were computed and analyzed. In sharp contrast to the findings by Werstiuk’s group, two-electron, three-center bonding structures were found with the charge largely and similarly distributed over the three carbon centers. Bond lengths for two C–C bonds are 1.84 Å and the third C–C bond is 1.40 Å. The computed chemical shift values agree with the experimental values within a difference of 3.2 ppm.

\subsection*{3.5.2.3. The 7-Norbornyl Cation.} 7-Norbornyl derivatives were found to be extremely unreactive in solvolysis studies and product formation was shown to occur with predominant retention of configuration.\(^\text{917–920}\) These observations led to the suggestion by Winstein et al.\(^\text{917}\) that the cationic intermediate is a nonclassical ion. Attempts to isolate the 7-norbornyl cation under stable ion conditions in superacid
media, however, failed: both 7-chloronorbornane (513) and the isomeric 3-chlorobicyclo[3.2.0]heptane (514) afforded the 2-norbornyl cation.

Subsequently, Sunko, Schleyer, and co-workers\textsuperscript{921} succeeded in observing the 7-norbornyl cation using the cryogenic matrix isolation technique. When 7-chloronorbornane 513 and a large excess of SbF$_5$ were co-deposited at $-263^\circ$C and slowly warmed to $-173^\circ$C, the IR signals indicated the formation of the 7-norbornyl cation 489 (Scheme 3.21). Further warming gave the 2-norbornyl cation 504 at $-73^\circ$C. The IR spectrum was in very good agreement with the calculated frequencies for the 7-norbornyl cation \[\text{[MP4(sdq,fc)/6-31G*/MP2(full)6-31G*+ZPE level].}\] The possibility of the formation of a complex of 513 with SbF$_5$ was ruled out when similar experiments with both 513 and 514 resulted in identical spectra. Recent \textit{ab initio} calculations\textsuperscript{916} support the nonclassical bent structure of the cation.

### 3.5.2.4. The 2-Bicyclo[2.1.1]hexyl Cation.

The bicyclo[2.1.1]hexyl cation 515 was first observed by Wiberg and co-workers\textsuperscript{922} in superacidic media by $^1$H NMR spectroscopy. From the observed chemical shift data, they suggested a symmetrically bridged structure (516) for the ion, although they could not freeze out the degenerate equilibria. Similar conclusions were drawn from solvolytic studies.\textsuperscript{923,924}

In a subsequent $^{13}$C NMR study, Olah, Liang, and Jindal\textsuperscript{925} concluded that there is very little $\sigma$-bridging in the rapidly equilibrating ion. The $^1$H NMR spectrum of the ion 515 in SbF$_5$–SO$_2$ClF showed three resonances at $\delta^1$H 8.32 (two protons), 3.70 (six protons), and 2.95 (one proton) with no significant line broadening down to $-140^\circ$C.
The $^{13}$C NMR spectrum of the ion $515$ also shows three resonances at $\delta^{13}$C 157.8 [doublet, $J_{C-H} = 184.5$ Hz; C(1) and C(2)], 49.1 [triplet, $J_{C-H} = 156.9$ Hz; C(3), C(5), and C(6)], and 43.4 [doublet, $J_{C-H} = 164.6$ Hz; C(4)]. Above $-90$°C the ion irreversibly rearranges to the cyclohexenyl cation.

A study by Saunders, Wiberg, and co-workers$^{926}$ involving deuterium labeling at the exchanging sites indicates that there is significant $\sigma$-bridging in the ion $515$. Schmitz$^{927}$ and Sorensen have shown that the free-energy difference between cations $515$ and $517$ is 7–9.8 kcal mol$^{-1}$ compared with 5.5 and 11.4 kcal mol$^{-1}$ for the analogous 2-norbornyl and cyclopentyl cations substantiating the intermittent (partially bridged) nature of the ion $515$.

An unequivocal support for the existence of interconverting bridged ions has come from labeling experiments by Kirmse et al.$^{928}$ including the use of the double-labeled [2-$^2$H,3-$^{13}$C] derivative. Further support was provided by ab initio calculations$^{929}$ [MP(full)/6-31G* level] indicating that both $515$ and $516$ are energy-minimum structures but $516$ is favored over $515$ by 4 kcal mol$^{-1}$. Structure $516$ is also supported by a comparison of experimental and calculated (IGLO) $^{13}$C NMR chemical shifts values.$^{929,930}$

Attempts to prepare$^{931}$ the analogous bicyclopentyl cation $518$, however, were unsuccessful and instead gave the rearranged cyclopentenyl cation $73$.  

3.5.2.5. Degenerate Cyclopropylmethyl and Cyclobutyl Cations. In contrast to the “classical” tertiary and secondary cyclopropylmethyl cations (showing substantial charge delocalization into cyclopropane ring but maintaining their identity), primary cyclopropylmethyl cations rearrange to cyclobutyl and homoallylic cations under both solvolytic and stable ion conditions.$^{18,195,196,932–934}$ The nonclassical nature of cyclopropylmethyl and 1-methylcyclopropylmethyl cations $519$ and $520$ is now firmly established.$^{171–176,935–940}$ Wide-ranging studies showed$^{201,212–214}$ that the cyclopropyl group is equal to or better than a phenyl group in stabilizing an adjacent carbocationic center. The direct observation of cyclopropylmethyl cations provides a clear example of positive charge delocalization into a saturated $\pi\sigma$-hydrocarbon system. The majority of the secondary cyclopropylmethyl cations, however, undergo degenerate equilibria.$^{941–943}$

The cyclopropylmethyl cation $519$ can be generated from allylic, cyclobutyl, and cyclopropylmethyl precursors (Scheme 3.22). The $^1$H NMR spectrum is shown in Figure 3.24.

At the lowest temperatures studied ($\sim-140$°C), $^{13}$C NMR spectroscopy indicates that $519$ is still an equilibrating mixture of bisected $\sigma$-delocalized cyclopropylearbinyl cations $521$ and bicyclobutonium ion $522$. $^{171,172}$ From the comparison of calculated NMR shifts, the low-lying species is considered to be the bicyclobutonium ion.$^{171,172}$
A similar conclusion has been reached by Saunders, Roberts, and co-workers based on isotopic perturbation studies.
The same conclusion was reached by calculations using the IGLO method on the MP2/6-31G* optimized geometries. Cations 521 and 522 were found to equally stable isomers lying 9.0 kcal mol\(^{-1}\) higher than the global minimum (1-methylallyl cation) reported in computational studies [MP4/6-311G**//MP2/6-31G*+ZPVE level]. Additional studies using ultralow-temperature CP-MAS NMR and results of the IR spectra of C\(_4\)H\(_7\)\(^+\) at 180 K in SbF\(_5\) matrices in combination with MP2/6-31G* calculations also support these conclusions. Cacace et al. have recently found that in the gas phase and in a gaseous microsolvated environment the equilibrium ratio of 521/522a+522b is very close to unity and equilibration occurs within a time interval of \(\leq 10^{-10}\) s (FT–ICR mass spectrometry and high-pressure radiolytic techniques).

\[
\begin{array}{c}
\text{522a} \quad \text{H} \quad \text{521} \quad \text{522b}
\end{array}
\]

C\(_4\)H\(_7\)\(^+\) ions were generated by collisionally activated dissociation (CAD) in the gas phase from various precursors. Mass spectrometric analysis showed that homoallyl chloride and cyclopropylmethyl chloride generated primarily cation 521, whereas cyclobutyl chloride gave a substantial amount of bicyclobutonium ion 522.

However, in the case of C\(_5\)H\(_9\)\(^+\) 520, the low-lying species are the nonclassical methylbicyclobutonium ions 523 with no contribution from either the bisected 1-methyl-1-cyclopropylmethyl cation 524 or the 1-methylcyclobutonium cation 48a. The highly shielded \(\beta\)-methylene resonance at \(\delta^{13}\text{C} = -2.81\) in the \(^{13}\text{C}\) NMR spectrum is particularly convincing evidence for the nonclassical bicyclobutonium structures. Support for the bridged structure 525 comes from deuterium isotope perturbation studies. The 1-ethyl and 1-propyl analogs of 520 are similarly nonclassical but rearrange irreversibly upon warming to cycloalkyl cations.
The potential energy surface of the analogous C$_7$H$_{11}^+$ cation with the built-in C$_4$H$_7^+$ bicyclobutonium subunit has recently been investigated by $ab$ initio (MP2/6-31G*) and DFT (B3LYP/6-31G*) calculations. The pentacoordinated unsymmetrical bicyclobutonium ion 526 was found to be the global minimum, but the boat conformer of cyclopropylcarbinyl cation 527 is only less stable by 0.8 kcal mol$^{-1}$. With the larger basis set or higher level of the MP method, the gap between the two cations decreases further.

Siehl and co-workers have used the matrix co-condensation technique to generate the 1-(trimethylsilyl)bicyclobutonium ion 528 (Scheme 3.23). The $^1$H and $^{13}$C NMR spectra of ion 528 show averaged methylene signals, which is in accord with a fast threefold degenerate rearrangement and a puckered hypercoordinate structure.

The same technique was used to generate the 1-(tert-butyldimethylsilyl)bicyclobutonium ion 529, which undergoes fast 1,3-hydride shift upon increasing temperature to yield 3-endo-(tert-butyldimethylsilyl)bicyclobutonium ion 530 [Eq. (3.135)]. Ion 530 has a static structure, which is due to the efficient stabilization by the γ-endo-trialkylsilyl substituent.

Schmitz and Sorensen have prepared the primary cyclopropylmethyl cation 531 which shows static behavior. The nortricyclylmethyl cation 531 is regarded as a vinyl
bridged 2-norbornyl cation 531b. The support for the structure comes not only from $^1$H and $^{13}$C NMR studies but also from molecular orbital calculations.  

Ionization of alcohol 532 (Scheme 3.24) and diol 536 [Eq. (3.136)] precursors to generate the corresponding triaxane-2-methyl cation and ditriaxane-2,2-dimethyl dication, respectively, have been explored by Olah, Prakash, and co-workers. $^{953,954}$ $^{13}$C NMR characteristics of the ion generated from alcohol 532 (SbF$_5$–SO$_2$ClF, −78°C) are in accordance with a static classical, bisected cyclopropylmethyl cation (533), a fast equilibrium between nonclassical, unsymmetrically bridged bicyclobutonium ions (534a and 534b), or a fast equilibrium of classical protoadamantyl cations (535a and 535b) (Scheme 3.24). A comparison of calculated and experimental $^{13}$C NMR shift values, however, excludes ion 533. This and the application of the $^{13}$C chemical shift additivity concept giving a $\Delta \delta^{13}$C value of 226 indicate that the most likely structure for the cation is a set of rapidly equilibrating bridged bicyclobutonium ions (534a and 534b).

Because the geometry of 536 is similar to that of 532, similar spectral features can be expected. The only exception is that the two distonic positive charges result in a higher atom-to-charge ratio and, consequently, a lower extent of $\sigma$ delocalization into the strained cyclopropyl moieties. Ionization of 536 was performed under similar conditions $^{953,954}$ [Eq. (3.136)]. In accordance with expectations, the $^{13}$C NMR spectroscopic features (deshielding of the methylenes by 71 ppm compared to that of 534a and 534b) indicate higher positive charge density and lower degree of charge delocalization. However, this value is still relatively shielded by 72.5 ppm when compared to the nortricyclylmethyl cation (531); that is, charge delocalization is still
substantial ruling out the static bisected structure 537. The lack of temperature dependence of chemical shifts and the calculated $^{13}$C chemical shift additivity value ($\Delta \delta^{13}$C = 250 per positive charge) support the bicyclobutonium-type nonclassical structures 538a–538c.

Prakash, Olah, and co-workers\textsuperscript{209} succeeded in preparing the stable persistent tertiary cyclobutylidicyclopropylmethyl cation 69 by ionizing the corresponding alcohol (see Section 3.4.4). Primary and secondary cyclobutylmethyl cations, in turn, are nonclassical in nature and rearrange to thermodynamically more stable cyclopentyl cations. In a recent \textit{ab initio} study (MP2/6-31G* and MP2/cc-pVTZ levels)\textsuperscript{955} the authors have found that the primary cyclobutylmethyl cation with a $\sigma$-bridged nonclassical structure is an energy minimum on the potential energy surface. Charge delocalization into the cyclobutyl ring is evidenced by the significant elongation of the C(1)–C(2) bond (1.903 Å) which is comparable to that of the C(2)–C(Me) bond (1.738 Å). Two structures of energy minima were also identified for the secondary 1-cyclobutylethyl cation. Conformer 539a with \textit{exo} methyl group is more stable than conformer 539b (\textit{endo} methyl) (MP2/cc-pVTZ//MP2/cc-pVTZ+ZPE level), by 1.2 kcal mol\textsuperscript{−1}. The elongated, almost equal, bond distances of conformer 539a clearly show its true nonclassical nature [C(1)–C(2) = 1.837 Å, C(2)–C(5) = 1.822 Å]. The shorter C(1)–C(2) bond distance of conformer 539b (1.819 Å) indicates its relatively lower stability [C(2)–C(5) = 1.839 Å]. Calculated $^{13}$C NMR shift data ($\delta^{13}$C 154.1 and 142.2 for 539a and 539b, respectively)—that is, the larger deshielding of conformer 539a—again reflect its relatively higher nonclassical stabilization.

### 3.5.2.6. Shifts to Distant Carbons

Although there are many examples of 1,2-hydrogen and alkyl shifts, the occurrence of 1,3, 1,4, and 1,5 shifts must also be considered. A sequence of 1,2 shifts, however, can often yield the same results as a 1,3 or 1,4 shift, and the unambiguous demonstration of such can be difficult.
Hydrogen-Bridged Acyclic Ions. The 2,4-dimethylpent-2-yl cation $8$ is able to undergo a degenerate 1,3-hydrogen shift$^{956, 957}$ ($E_a = 8.5 \text{ kcal mol}^{-1}$). The alternative mechanism of the successive 1,2-hydrogen shift can be eliminated in this case, since line broadening of methyl peak but not methylene peak occurs (in the NMR spectrum) in the temperature range of $-70^\circ \text{C}$ to $-100^\circ \text{C}$. A third possible mechanism involving a corner-protonated cyclopropane $540$ is highly unlikely based on energy estimates.$^{97}$

A similar activation energy barrier of 10.5 kcal mol$^{-1}$ is found for 1,3-hydrogen shift in 1,3-dimethylcyclohexyl cation $541$$^{958}$; incorporation of the six-membered ring constrains the transition state and raises the activation energy barrier.

An activation energy barrier of 12–13 kcal mol$^{-1}$ was estimated for the 1,4-hydrogen shift in 2,5-dimethyl-2-hexyl cation $542$ using magnetization transfer techniques.$^{957}$ The possibility of protonated cyclobutane intermediate similar to the previously considered protonated cyclopropane intermediate is highly unlikely. A similar degenerate 1,4-hydrogen shift is found to occur in the 1,4-dimethyl-1-cyclohexyl cation $543$. The occurrence of successive 1,2- or 1,3-hydrogen shifts was clearly ruled out from a variable temperature NMR study. The activation energy barrier for such a process was estimated at 13 kcal mol$^{-1}$.

Intrigued by facile transannular hydride transfers in medium-sized rings,$^{959–963}$ Saunders et al.$^{56}$ examined the 2,6-dimethylheptyl cation $544$. Even at the lowest
temperature studied (about −100°C), the ion exhibits a single averaged peak for the four methyl groups, implying that the 1,5-hydrogen shift occurs with an activation energy barrier of 5 kcal mol⁻¹ or less or the ion could have a symmetrically structure such as 545.

Sun and Sorensen⁹⁶⁴ have successfully prepared mono- and di-µ-hydrido-bridged carbodications 546a–546c by reacting the corresponding diols with FSO₂H–SbF₅ in SO₂ClF. NMR characterization data are shown in Table 3.7.

Dication 546a showed an NMR spectrum with a single shielded ¹H signal (Table 3.7), although the signal is not as shielded as reported for the cyclic µ-hydrido structures. Furthermore, the signal is highly temperature-dependent, which is characteristic of rapidly equilibrating systems. It appears that the bulky isobutyl group at C(4) in the chain affects significantly the chain conformation allowing for an equilibrium between the µ-hydrogen bridged 546a and the unbridged structure 546a’. Disubstitution at C(4) (structure 546b) results in a similar equilibrating dicationic mixture. The NMR characteristics of 4,4-diisobutyl-substituted dication 546c (highest upfield shift, triplet for the bridging centers, J_H-¹³C ≈ 20 Hz) indicate that 546c exists as a di-µ-hydrido-bridged system, the first of its kind. The two hydride

⁹⁶⁴Two protons.
hydrogens undergo very rapid mutual exchange via unbridged species present in low concentration.

**Hydrogen-Bridged Cycloalkonium Ions.** The studies of Prelog and Traynham\textsuperscript{959} and Cope et al.\textsuperscript{960} established that medium-sized cycloalkyl rings (C\textsubscript{8} to C\textsubscript{11}) undergo direct transannular hydride shifts in reactions involving an electrophilic (i.e., carbocationic) intermediate.\textsuperscript{965} Sorensen and co-workers\textsuperscript{966} have shown that at very low temperature (−130°C) the cyclodecyl cation exists as a static 1,6- or 1,5-hydrido structure \textbf{547c} or \textbf{547e}, respectively. Similar behavior was also observed for the 1,6-dimethyl analog \textbf{548}.\textsuperscript{967} The bridging hydrogen in ion \textbf{547c} is observed at an unusually high field of $\delta^{1}\text{H} = −6.85$.

Stable hydrogen-bridged cycloalkyl cations \textbf{547a}, \textbf{547b}, and \textbf{547d} (8-, 9-, and 11-membered rings) have subsequently been observed.\textsuperscript{968} The bridging hydrogen was found to be increasingly more shielded in the $^{1}\text{H}$ NMR spectra as the ring size was increased. This indicates increased negative charge on the bridged hydrogen (conversely increased positive charge on the terminal hydrogens) as the distance of separation between the bridged carbons is increased. The $^{1}\text{H}$ NMR shifts of the terminal and bridging hydrogens of various hydrogen-bridged carbocations are shown in Table 3.8.

Sorensen and co-workers also obtained evidence for 1,5-\(\mu\)-hydrido bridging between secondary and tertiary carbon sites in several substituted cyclooctyl cations. The \(\mu\)-1,5-bridged 1,5-dimethylcycloodecyl cation 549 has also been obtained and studied as a distinct stable species. Application of Saunders’ isotopic perturbation technique to ion 548 confirmed the bridged structure. With one trideuteromethyl group, an isotopic splitting of only 0.6 ppm is observed in the \(^{13}\text{C}\) resonance of bridged carbon, and this clearly supports the assigned hydrido-bridged structure.

McMurry and co-workers have successfully prepared the unique \(\mu\)-hydrido bridged cation 550 in \textit{in situ}-bicyclo[4.4.4]tetradecane by protonating the bridgehead alkene in relatively weak trifluoroacetic acid or reacting the corresponding saturated precursor with triflic acid. [Eq. (3.137)]. This hydrogen-bridged propellane cation (550) is remarkably stable in acid solution even at room temperature. The bridgehead carbon appearing at \(\delta^{13}\text{C} 139.3\) in the \(^{13}\text{C}\) NMR spectrum is far shielded for a classical cation. The \(^{13}\text{C}\) NMR of the 2-deuteriated cation showed a splitting of 0.8 ppm with a very small temperature dependence, whereas the \(^{2}\text{H}\) NMR of the cation with bridgehead deuterium gave a chemical shift of \(\delta^{2}\text{H} – 3.36\) (0.1 ppm deshielded from the unlabeled ion). These data are indicative of a nonclassical structure with a 3c–2e bond.

\]

An extensive computational study [BLYP/6-31G(d,p) level, AIM and NBO theories] by DuPré has shown that charge distribution in cation 550 prevents the development of unstable bridgehead carbocation. They also found that atoms across the \(\text{C}--\text{H}--\text{C}\) bonding are nearly neutral because of electron delocalization and the bridging hydrogen has essentially 1s electron configuration and thus highly shielded in the \(^{1}\text{H}\) NMR spectrum.

Subsequently, cations with a range of different ring sizes (551–553) were prepared and studied both experimentally and computationally. The expectation that smaller ring size would result in more bent three-center bond was fulfilled when calculated data (AM1 level) showed significant bending and changes in \(\text{C}--\text{H}\) bond.
lengths (Table 3.9). Furthermore, the chemical shift of the bridging hydrogen becomes more shielded with increasing C–H–C bond angle indicative of an overall polarization of the bond. The deshielding in the $^{13}$C NMR shifts indicates decreasing bridging with decreasing ring size. Ions 551 and 552 have stabilities similar to that of 550. In contrast, ion 553 is stable only below 10°C and its NMR spectrum is temperature-dependent with two high-shielded absorptions at $-50°C$ ($\delta^1H = 6.4$ and $-6.5$).

The effect of distance between the carbon centers on the nature of the 3c–2e bonds has been studied by Sorensen and Whitworth in the tricyclic systems 554 prepared from the corresponding bridgehead alkenes. The NMR spectra of the unconstrained cation 555 studied for comparison showed the presence of two classical structures in equilibrium. The chemical shift of the interchanging hydrogen ($\delta^1H = 0.30$) indicates a shielded hydrogen but not sufficient enough for a $\mu$-bridged hydrogen.

Ions 554a and 554b were generated by protonation in HSO$_3$F–SbF$_5$, and they were stable below $-20°C$. The NMR spectral data of cation 554a (Table 3.10) are characteristic of a classical tertiary carbocation. Although the changes in the $^1H$ and
$^{13}$C NMR shifts of cation 554b indicate the onset of bridging, MINDO/3 calculations for the lowest energy conformers gave classical structures for both cations. Cations 554c and 554d were generated in HSO$_3$F–TFA, and they were stable at room temperature. The NMR spectra of both cations show the features of nonclassical bridged structures. The temperature dependence of cation 554c indicates the presence of two isomers: one symmetrical (minor) and the other (major) with less symmetrical bridging. Experimental data and calculations for these two ions do not agree well. The structure of lowest energy for 554c was found to be a classical cation and the bridging structure of lowest energy is 5.1 kcal mol$^{-1}$ less stable. The lowest energy structure for 554d, in turn, is a $\mu$-hydride bridged structure. However, an unsymmetrical $\mu$-bridged ion lies higher in energy only by 0.45 kcal mol$^{-1}$.

The 5-pentacyclo[6.2.1.1$^3,6$,$^2,7$.$^0,4,10$]dodecyl cation has been suggested to be the intermediate in the solvolysis and rearrangement of pentacyclododecane derivatives. Recent computational studies have shown that the $\mu$-hydride bridged cation 556 is the structure of the lowest energy [MP2/6-31g(d,p)]. The C–H bond length is 1.261 Å, the C–C bond distance is 2.109 Å, and the C–H–C bond angle is 113.5$^\circ$. A second minimum is the nonclassical cation 557 with the 3c–2e bond lying 3.3 kcal mol$^{-1}$ higher than 556 [B3LYP/6-31g(d,p)].

**Five-Center Four-Electron Bonding Structures.** The potential for the existence of 5-center 4-electron (5c–4e) bonding structures 558 have recently been surveyed by Tantillo and Hoffmann$^{980}$ [calculations at the B3LYP/6-31G(d) level]. A cation with three anthracenyl units joined around the C–H–C–H–C core with two approximately trigonal pyramidal carbon atoms and one five-coordinate trigonal bipyramidal carbon was found to have 5c–4e bonding. The anticipated existence of
such cations has been strongly supported by an independent generalized population analysis.\textsuperscript{981} The same method has been applied\textsuperscript{982,983} to explore the nature of bonding in cation 559 with tetracoordinated proton sandwiched between two C–C double bonds with the 5c–4e bonding residing in the C⋯C⋯H⋯C⋯C fragment. The results further corroborate the possible occurrence of delocalized 5c–4e bonding.

![Chemical structures](image)

3.5.2.7. 9-Barbaralyl (Tricyclo[3.3.1.0^2,8]nona-3,6-dien-9-yl) Cations and Bicyclo[3.2.2]nona-3,6,8-trien-2-yl Cations. The 9-barbaralyl cation 560 is the cationic counterpart of bullvalene 561. The unique stereoelectronic composition of the structural elements of 560 suggests that it is very reactive in both degenerate (partial and total) and nondegenerate rearrangements. Bullvalene shows total degeneracy through a series of Cope rearrangements.\textsuperscript{984} There are several intriguing structural and mechanistic questions connected with the barbaralyl cations; for example, what are their structures and how does the positive charge influence the degenerate Cope rearrangement in ion 560? Ion 560 is closely related to the bicyclo[3.2.2]nona-3,6,8-trien-2-yl cation 562, which has been of interest in connection with the development of the concept of bicycloaromaticity.\textsuperscript{985}

![Chemical structures](image)

When bicyclo[3.2.2]nonatrien-2-ol 563 was treated with superacid at $-135^\circ$C and observed at the same temperature by $^1$H NMR spectroscopy, a sharp singlet at $\delta^1$H 6.59 was obtained. A rapidly rearranging carbocation was inferred to be responsible for the observed singlet since there is no regular polyhedron with nine corners, that is, nine equivalent positions [Eq. (3.138)]. The chemical shift of the singlet compared with that estimated from appropriate reference compounds indicated that the ion that was rapidly exchanging all its nine CH groups was the 9-barbaralyl cation 560 rather than the bicyclo[3.2.2]nona-3,6,8-trien-2-yl cation 562. A combination of mechanism (IV) (Scheme 3.25) and mechanism (V) (Scheme 3.26) or structure 565 itself was proposed for the total degeneracy, and the rearrangement barrier was estimated to be $\sim$6 kcal mol$^{-1}$. Even at $-125^\circ$C, the singlet disappeared rapidly, and a novel type of ion, a
1,4-bishomotropylium ion, bicyclo[4.3.0]nonatrienyl cation 564 was quantitatively formed.\textsuperscript{45,986–988}

\[

\]
The total degeneracy was found to be slow on the $^{13}$C NMR time scale. No signal was detected above noise level in the spectrum. Thus, the signals must be very broad as a consequence of slow rearrangements.$^{54}$ In the hope of being able to solve controversies concerning the structure and mechanisms of rearrangement of the barbaralyl cation, the $^{13}$C-labeled precursor $566$ was synthesized and the $^{13}$C-labeled barbaralyl cation $567$ was prepared$^{989}$ [Eq. (3.139)].

The $^{13}$C NMR spectrum at $-135^\circ C$ showed a broad band at $\delta^{13}C$ 118.5 conforming the fast scrambling of all nine carbon atoms. The barrier was found to be 5.5 kcal mol$^{-1}$. Upon lowering the temperature to $-150^\circ C$, the signal broadened and split into two new signals at 101 ppm and 152 ppm with the area ratio 6:3. Further lowering of the temperature to $-152^\circ C$ sharpened the signals. These results exclude ion $562$ as the observed ion. However, the data do not allow discrimination between the two proposed ions $560$ and $565$. If rearrangement (IV) gives the area ratio 6:3, the barrier for such a rearrangement is estimated to be $\leq 4$ kcal mol$^{-1}$. The static ion $565$ should also show the area ratio observed.

Subsequently, the controversy was solved by Ahlberg and co-workers$^{990,991}$ using a combination of $^{13}$C labeling and isotopic perturbation. The specifically octadeteriated and $^{13}$C-labeled precursor $568$ was synthesized, and reaction with superacid gave the $(CD)_8^{13}CH^+$ cation $569$ [Eq. (3.140)]. The $^{13}$C NMR spectrum of $569$ is similar to that of $567$ but has some important differences. The broad singlet observed from $569$ at $-135^\circ C$ appeared 4.5 ppm downfield of that of $567$ and the two signals at $-151^\circ C$ had also been shifted; the low-field one had been shifted to upfield by $\sim 1$ ppm and the high-field one downfield by 6 ppm. Furthermore, the area ratio had changed from 6:3 to 5:3. These changes caused by the isotopic perturbation are only consistent with the labeled perturbed ion being a 9-barbaralyl cation $560$ and not the $D_3h$ structure $565$.

If the ion $569$ has structure $565$, the following spectral changes would have been expected. Due to equilibrium (VI) (Scheme 3.27), which is likely to have an equilibrium constant smaller than 1 because of the difference in zero-point energy between a “cyclopropane” C–H and “olefinic” C–H, a downfield shift of the singlet might be observed. The two signals at $-151^\circ C$, on the other hand, are not expected to
shift relative to those of 567, since the six “cyclopropane” carbon–hydrogen bonds are equivalent and so also are the three “olefinic” carbon–hydrogen bonds. However, an area ratio different from 6:3 is expected.

If, on the other hand, 569 has the 9-barbaralyl cation structure 560, the observed shifts of the two signals at \(-151^\circ\text{C}\) are as expected: The carbon–hydrogen bonds involving C(1), C(2), C(4), C(5), C(6), and C(8) are not equivalent and therefore \(^{13}\text{C}\)-H will preferentially be found in olefinic position since olefinic C–H bonds have lower zero point energy than saturated C–H bonds. Therefore, the \(^{13}\text{C}\) average chemical shift will be shifted downfield [by process (VII), Scheme 3.52]. By the same reasoning, only a minor shift is expected for the C(3), C(7), and C(9) group involving olefinic carbon–hydrogen bonds. The observed shift at \(-135^\circ\text{C}\) of the broad singlet is also as expected. Thus, the barbaralyl cation has 9-barbaralyl cationic structure 560 and undergoes the sixfold degenerate rearrangement (IV) (Scheme 3.25), which has a barrier of only 4 kcal mol\(^{-1}\). Structure 565 has been excluded as either transition state or intermediate in this rearrangement.\(^{990}\)

Complete degeneracy of ion 560 is probably achieved through mechanism (V) (Scheme 3.26), where ion 562 is either an intermediate or transition state.\(^{992}\)

Similar rearrangements are also observed in 9-substituted and 4,9-dimethyl-substituted 9-barbaralyl cations. The mechanisms of such rearrangements have been thoroughly investigated.\(^{993-995}\)

\textit{Ab initio} studies have been performed to explore the potential energy surface of the \(\text{C}_9\text{H}_9^+\) cations.\(^{996-998}\) Calculations by Ahlberg, Cremer, and co-workers\(^{998}\) have shown [MP2, MP3, and MP4(SDQ) with 6-31G(d) basis set] that 9-barbaralyl cation 560 is more stable than nonclassical barbaralyl cation 565 and bicyclo[3.2.2]nona-3,6,8-trien-2-yl cation 562 by 6.9 and 4.6 kcal mol\(^{-1}\), respectively. Both sit at a transition state or in a very shallow minimum surrounded by transition states of similar energies. The energetically most favorable transformations of 560 are sixfold degenerate rearrangements via transition state 570 of \(C_2\) symmetry representing an activation energy barrier of 3.6 kcal mol\(^{-1}\). A new reaction mechanism has been suggested to interpret the complete degenerate rearrangement of 560 leading to equilibration of all carbon atoms.
It is characterized by double-bifurcation reactions with three directly connected first-order transition states. These are two transition states 570 and transition state 562. The chemical behavior of cation 560 is determined by the stereocomposition of a cyclopropylcarbonyl cation moiety in conjugation with two vinyl groups. The 9-barbaralyl cation 560 is characterized by four weak C–C single bonds (bond orders = 0.54 and 0.84) and one strong nonbonded interaction that can be easily broken and closed.

3.5.2.8. The 1,3,5,7-Tetramethyl- and 1,2,3,5,7-Pentamethyl-2-adamantyl Cations. The nature of the 2-adamantyl cation 571 has been difficult to study under stable ion conditions since it undergoes facile rearrangements to the more stable 1-adamantyl cation 49. This difficulty was circumvented by Lenoir, Schleyer, Saunders, and co-workers by blocking all four bridgehead positions by methyl groups in a study of 1,3,5,7-tetramethyl- and 1,2,3,5,7-pentamethyl-2-adamantyl cations 572 and 573.

The $^1$H NMR spectrum of 572 in superacid had the correct number of peaks to fit the symmetry of a static 2-adamantyl cation, but the chemical shift of the CH proton at the presumed carbocation center C(2) was $\delta^1$H 5.1. This is 8 ppm to higher field than expected for a typical static secondary carbenium ion such as the isopropyl cation 2. Since the symmetry of the spectrum was incompatible with either a static bridged 2-adamantyl cation 574 or a static protoadamantyl cation 575, two mechanisms were postulated involving sets of 574 or 575 undergoing rapid degenerate rearrangements at $-47^\circ$C [Eqs. (3.141) and (3.142)].
Apart from one of these degenerate rearrangements, 572 also underwent a non-degenerate rearrangement to the more stable tertiary 2-adamantyl cation 577 with a half-life about 1 h at −47°C [Eq. (3.143)]. The kinetics of this rearrangement, which involves protoadamantyl cations 576 as intermediates, was advantageously studied in the tertiary 2-adamantyl system 573, where it is degenerate. Line-shape analysis for the degenerate rearrangement of 573 gave $E_a = 12.1 \pm 0.4 \text{ kcal mol}^{-1}$ in accord with molecular mechanics calculations.

\[
\begin{align*}
572 & \iff 576 \iff 573 \iff 577 \\
\text{(3.143)}
\end{align*}
\]

Since it was difficult to make an exclusive choice between mechanisms for the degenerate rearrangement shown in Eqs. (3.141) and (3.142) and the average structure of 572 on the basis of $^1$H NMR data only, further arguments were taken from a solvolytic study, and the mechanism involving 574 [Eq. (3.141)] was preferred as an explanation for the behavior of 572 in superacid.

Criticism of these conclusions by Fărcașiu led Schleyer, Olah, and co-workers to study 572 and 573 further by $^{13}$C NMR spectroscopy. The spectra of 573 confirmed its classical static carbenium ion structure at low temperature. At 30°C an average of the C(1), C(2), and C(3) signals and those of the CH$_3$ groups attached to these positions, respectively, were observed due to the degenerate rearrangement via the mechanism in Eq. (3.142).

An entirely different spectrum was obtained for 572 with the C(2) $^{13}$C resonance at $\delta_{^{13}C} 92.3$, more than 200 ppm removed from the position expected for a static classical cation. Since a static structure like 572 was incompatible with the observed spectrum, a chemical shift estimate was made for the protoadamantyl cation 575. However, the discrepancy between these estimated chemical shifts and those observed was too large to explain the behavior of the 1,3,5,7-tetramethyl-2-adamantyl cation within the properties of an equilibrating set of ions 575 even with the partial contribution of 572. This left the set of $\sigma$-bridged ions 574 equilibrating according to the mechanism in Eq. (3.141) as the only possible structure for this ion.

### 3.5.3. Homoaromatic Cations

The concept of homoaromaticity $^{29,1001–1006}$ was advanced by Winstein in 1960. It represented a challenge to experimental and theoretical chemists alike. $^{1007–1009}$ The question of homoaromatic overlap has been mainly studied in six-$\pi$-electron Hückeloid systems, $^{29,1001–1006}$ although several two-$\pi$-electron homoaromatic systems have been discovered subsequently. $^{230,1006,1010–1013}$
Theoretical studies have recently been performed to find appropriate criteria for homoaromaticity of carbocations. Using four criteria [aromatic ring-current shielding (ARCS), nucleus-independent chemical shifts (NICS), bond-length alterations, and $^1$H NMR shielding], cations $C_8H_9^+$, $C_9H_{10}^+$, and $C_{12}H_{13}^+$ were found to be the most homoaromatic. No other molecules are ranked as homoaromatic by all four criteria. For homoaromatic molecules of small ring size, the ARCS method is the method of choice to assess homoaromaticity. Interestingly, a $C(1)–C(n–1)$ distance of about 2 Å seems to be a good indication of homoaromaticity.

3.5.3.1. Monohomoaromatic Cations. The simplest $2\pi$ monohomoaromatic cation, the homocyclopropenyl cation ($C_4H_5^+$, cyclobutenyl cation, 578), along with its analogs, has been prepared and studied by Olah et al. The experimental evidence for the existence of 1,3-overlap has been derived from $^1$H and $^{13}$C NMR data. At low temperature, the methylene protons of the ion 578 exhibit non-equivalence, indicating ring puckering. The experimentally determined barrier for ring flipping of 8.4 kcal mol$^{-1}$ compares closely with the theoretical estimates. Subsequent computational studies by Schleyer and co-workers have confirmed the bent structure of 578. Ring inversion energies calculated at various levels of theory were found to be 9.0–9.3 kcal mol$^{-1}$, which agree well with experiment. The homoaromatic character of ion 578 is shown by the nearly equal charges on $C(1)$, $C(2)$, and $C(3)$, the considerable bond order, the short $C(1)–C(3)$ bond distance (1.74 Å), and the large stabilization energy relative to the methylallyl cation. Long-lived polysubstituted cations 579 have recently been generated from the corresponding methylenecyclobutenes in $HSO_3F–SbF_5–SO_2ClF$ solution at $–130^\circ$C and characterized by $^1$H and $^{13}$C NMR spectroscopy.

Other examples of monohomoaromatic cations are the $6\pi$ homotropylium ion 179 of Pettit and Winston and the previously discussed $2\pi$ homoaromatic 11-methyltricyclo[4.4.1.0$^{1,6}$]undec-11-yl cation 46.

The structure and properties of the homotropylium ion 179 of Cs symmetry have been addressed theoretically. Both MP2(full)/6-31G* and MMP2 geometries give almost perfect C–C bond equalization in the seven-membered ring moiety. This observation, the strong stabilization (–22.8 kcal mol$^{-1}$) by the $\pi$ overlap, and the short $C(1)–C(7)$ bond distance (1.957–2.149 Å) indicate efficient electron delocalization involving through-space 1,7 interaction. Therefore, the homotropylium ion 179 is a truly homoaromatic six-$\pi$-electron system. The planar structure 580 (C$_{2v}$ symmetry) participating in ring inversion of cation 179, in turn, has a stabilization energy of only –2.1 kcal mol$^{-1}$ and, consequently, cannot be regarded as an aromatic system. Alkorta
et al.\textsuperscript{1027} have found in a recent study that fluorination has not much effect on the homoaromaticity, that is, homoaromaticity is a persistent property of the parent ion 179.

\[
\begin{array}{cc}

1 & 7
\end{array}
\]

\[
\begin{array}{cc}
\text{H} & \text{H} \\
\end{array}
\]

3.5.3.2. Bishomoaromatic Cations. The magnitude of homoaromatic stabilization is expected to decrease with increasing interruption by methylene groups of the otherwise conjugated $\pi$-framework in neutral molecules. However, in an ionic species, additional driving force is present for charge delocalization. Two of the most widely studied bishomoaromatic cations are the 7-norbornenyl and 7-norbornadienyl cations 581 and 582.\textsuperscript{1011,1028–1034}

\[
\begin{array}{cc}
\text{581} & \text{582} \\
\text{583}
\end{array}
\]

The $^{13}$C NMR spectrum of the cation 581 shows substantial shielding of both the C(7) cationic and vinylic carbon chemical shifts ($^{13}$C 34.0 and 125.9, respectively).\textsuperscript{1011} A similar shielding phenomenon is observed for ion 582. Interestingly, ion 582 undergoes a bridge-flipping rearrangement\textsuperscript{1029,1032,1033} as well as ring contraction–expansion through the intermediacy of bicyclo[3.2.0]heptadienyl cation 583. These two processes can result in scrambling of all seven carbon atoms.

\[
\begin{array}{cc}
\text{582} & \text{bridge flipping}
\end{array}
\]

Several studies, including the application of the tool of increasing electron demand,\textsuperscript{691,1030–1032} best describe ion 581 as a symmetrical bridged $\pi$-bishomocyclopropenium cation and not as a rapidly equilibrating pair of cyclopropylmethyl cations, such as 584. The observed unusually large $^{13}$C–1H coupling constants at the C(7) position of 581 and 582 (218.9 and 126.4 Hz, respectively) demonstrate the higher coordination of the carbocationic carbon. X-ray crystal structure analysis of the 7-phenyl-2,3-dimethyl derivative of the 7-norbornenyl ion showed short C–C distances of the carbons in the 3c–2e bonding (both are 1.86 Å).\textsuperscript{78} The X-ray crystal structure, the optimized geometry\textsuperscript{1035} (MP2FC/6-31G*), and calculated $^{13}$C NMR shift data\textsuperscript{78} agree well.
Olah, Prakash, and co-workers\textsuperscript{1036} have generated and characterized the sandwiched bishomoaromatic dication \textbf{585} [Eq. (3.144)]. The $^1$H NMR spectrum of the solution at $-80^\circ$C indicated that the species shows the same symmetry as the starting diol with chemical shifts of some of protons being more shielded. The $^{13}$C NMR spectra with significantly shielded absorptions [$\delta^{13}$C 131.7 (doublet, $J_{C-H} = 199.3$ Hz), 52.9 (doublet, $J_{C-H} = 219.2$ Hz), and 38.1 (doublet, $J_{C-H} = 169.6$ Hz)] indicate the highly symmetric dicationic structure \textbf{585}. Dication \textbf{585} can be considered as a four-$\pi$-electron bicyclo(polycyclo)aromatic system. The magnitude of the observed chemical shifts and the lack of temperature-dependent behavior rule out, respectively, rearranged structures and equilibrium processes.

Several studies\textsuperscript{1037–1041} on the hexamethylbicyclo[2.1.1]hexenyl cation have shown that the ion is best represented as a bishomoaromatic species \textbf{586} analogous to \textbf{581} and \textbf{582}. Laube and Lohse\textsuperscript{1042} succeeded in acquiring the X-ray crystal structure of the \textit{endo-586} ion and its 6-chloro derivative. An unusually strong 3$c$–2$e$ bond [$C(2)$–$C(3)$ = 1.406 Å, $C(2)$–$C(5)$ and $C(3)$–$C(5)$ = 1.741 Å] was found in the latter. The optimized geometry\textsuperscript{78} of \textbf{586} (B3LYP/6-31G*) agrees well with the experimental values. These observations unequivocally indicate that the hexamethylbicyclo[2.1.1]hexenyl cation is a nonclassical ion and the equilibrating ions can be excluded.

The extent of bishomoaromatic delocalization, as expected, is critically dependent upon structural geometry. Attempts to prepare the parent bishomoaromatic 4-cyclopentenyl cation \textbf{588} from 4-halocyclopentene \textbf{587} were unsuccessful.
They gave instead the cyclopentenyl cation. The lack of formation of bishomoaromatic ions from cyclopentenyl derivatives is mainly due to steric reasons. The planar cyclopentene skeleton has to bend into the “chair” conformation to achieve any significant overlap between the empty $p$ orbital and the $\pi$–$p$ lobe of the olefinic bond, which is sterically unfavorable. However, such conformation already exists in ions 581 and 582.

\[
\text{X} = \text{Cl, Br}
\]

(3.145)

Bishomotropylium cations are $6\pi$ homoaromatic cations. The first bishomotropylium cations, the 1-methyl-1,4-bishomotropylium ion and the parent ion 589, were generated and observed by Winstein and co-workers under superacid conditions.\textsuperscript{986,1044,1045} The intermediate identified\textsuperscript{991} as the barbaralyl cation 560 rearranged exclusively to cation 589 at $-116^\circ$C. Strong support for the homoaromatic character of 589 comes from the observed $^{13}$C NMR shifts and $^{13}$C–$^{13}$C coupling constants indicating that all nine carbons are $sp^2$-hybridized. Solvolytic experiments, in turn, favored the cis-8,9-dihydro-1-indenyl structure 590.\textsuperscript{1046} Subsequent calculations\textsuperscript{1047,1048} [HF/6-31G(d), MP2/6-31G//HF/6-31G, and MP2, MP3, MP4(SQD)/6-31G(d) levels] showed, however, that 589 has a folded structure. The folding angle and C(2)–C(9) and C(5)–C(7) interaction distances (93° and 2.1 Å, respectively) differ significantly from those in the classical structure 590 (114° and 2.34 Å). Further observations,—namely, large degrees of bond equalization (1.40 ± 0.01 Å) and charge delocalization, a similar strong equalization of $^{13}$C chemical shifts in the seven-membered ring [IGLO/6-31G(d)], and a bond order characteristic of an aromatic system—lend additional strong support to the nonclassical nature of ion 589.

Olah, Prakash, and co-workers in collaboration with Prinzbach have studied bishomoaromatic cage dications derived from pagodane (an undecacyclic hydrocarbon) and dodecahedrane cage hydrocarbons.\textsuperscript{385,1049} Oxidation of 591 and its valence isomer 592 by two-electron removal from the central cyclobutane ring resulted in the formation of paramagnetic solutions which, upon standing at room temperature, gave diamagnetic solutions of a unique, surprisingly stable species\textsuperscript{1050} [Eq. (3.146)]. The symmetry of the $^1$H and $^{13}$C NMR spectra (four peaks in each spectrum) and the extent of deshielding indicated that the species is ionic and has the same $D_{2h}$ symmetry.
of the parent pagodane. A crystalline material was isolated and fully characterized by X-ray, which showed that the product retained the integrity of the hydrocarbon skeleton. The NMR spectra, which were found to be temperature-independent down to −130°C, along with additional evidence as well as computational studies (SCF–MO calculations), firmly established the nature of dication 593 excluding the possibility of rapidly equilibrating processes. The bishomologous dication 594, in contrast, rearranges to the bisallylic dication 595 even at −130°C. Dication 593 is a novel four-center two-electron delocalized σ-bishomoaromatic species, which resembles two-electron Woodward–Hoffmann transition states and owes its unprecedented character to its specific rigid framework.

\[
\begin{align*}
\text{SbF}_5 & \text{SO}_2\text{ClF} \quad \text{−78°C} & \quad \text{SbF}_5 & \text{SO}_2\text{ClF} \quad \text{−78°C} \\
591 & \quad 593 & \quad 592
\end{align*}
\]

To further explore the limiting structural and energetic prerequisites for the unique σ-bishomoconjugation the structurally related seco-1,16-dodecahedradiene 596 and 1,16-dodecahedradiene 597 were also studied. For 596, only the corresponding bisallylic dication could be observed,\textsuperscript{1051,1052} whereas for 597 the dication could not be observed at all.\textsuperscript{1053} The σ-bishomoaromatic species 599, however, could be generated via electrochemical oxidation of alkene 598.\textsuperscript{1054}

\[
\begin{align*}
596 & \quad 597 & \quad 598 & \quad 599
\end{align*}
\]

Isopagodanes 600 and 602 were also studied under the usual oxidative conditions (SbF₅–SO₂ClF, −130°C, prolonged stirring) and both gave diamagnetic solutions as a result of two-electron oxidation.\textsuperscript{1055} The number of absorptions of the ¹H and ¹³C
NMR spectra (seven peaks in each spectrum) and the observed deshielding of protons and carbons relative to the neutral 600 established the $C_2v$ symmetrical $\sigma$-bishomoaromatic structure 601a and excluded a rapid equilibration with the degenerate 601b. The bishomoaromatic structure of 603 was established in an analogous way. *Ab initio* calculations (B3LYP/6-31G* level of theory) gave only one minimum on the corresponding hypersurfaces and also indicated the $C_2v$ symmetrical structure with the rectangular geometries of the central $C_4$ units. Computations by Schleyer and co-workers [MINDO/3, MNDO, AM1, and MC-SCF] gave further strong evidence for the nonclassical nature of pagodane dications excluding two rapidly equilibrating classical $C_2v$ structures and a diradical of $D_{2h}$ symmetry.

The novel four-center two-electron delocalized $\sigma$-bishomoaromatic species 593, 594, 599, 601a, and 603 are representatives of a new class of $2\pi$-aromatic pericyclic systems. These may be considered as the transition state of the Woodward–Hoffmann allowed cycloaddition of ethylene to ethylene dication or dimerization of two ethylene radical cations (Figure 3.25, 604). Delocalization takes place among the orbitals in the plane of the conjugated system, which is in sharp contrast to cyclobutadiene dication 605 having a conventional $p$-type delocalized electron structure (Figure 3.25).

Precedents of this type of bonding pattern are the assumed bicyclo[2.2.2]octane-1,4-diyl dication 606, which was found to be the monocation monodonor–acceptor

![Figure 3.25. Molecular orbital representations of the bonding structure of the parent bishomoaromatic dication $C_4H_8^{2+}$ (604) and cyclobutadiene dication $C_4H_4^{2+}$ (605).](image-url)
complex in a subsequent reinvestigation, and the octamethylnorbornadienediyldication prepared and characterized by Hogeveen and co-workers.

The nature of bonding in the parent \( \text{C}_4\text{H}_8^{2+} \) dication [tetramethylene dication \((\text{CH}_2)_4^{2+}\)] was analyzed by various levels of theory. Of the various species selected, the open form \( \text{608} \) with \( \text{C}_i \) symmetry was found to be the global minimum at all levels of theory. However, optimization with MINDO/3, AM1, and 3-21G for the classical pagodane dications \( \text{609a} \) and \( \text{609b} \) led to ring closure to the parent bishomoaromatic pagodane dication \( \text{593} \) of \( \text{D}_{2h} \) symmetry. IGLO \( ^{13}\text{C} \) NMR chemical shift calculations lend additional support for the bishomoaromatic stabilization. Apparently, despite the strain imposed by the planar cyclobutane moiety in the polycyclic cage structure, the strong Coulombic repulsion that could lead to geometric distortion and, consequently, cancellation of bishomoaromaticity is successfully counterbalanced by the rigid molecular framework thus contributing to stabilization.

3.5.3.3. Trishomoaromatic Cations. Following Winstein’s proposal of the formation of a trishomoaromatic cation in the solvolysis of \( \text{cis-bicyclo[3.1.0]} \) hexyl tosylate, extensive effort was directed toward its generation under stable ion conditions. Masamune et al. were first able to prepare the ion \( \text{610} \) by the ionization of \( \text{cis-3-chlorobicyclo[3.1.0]} \) hexane in the superacidic media. Subsequently, it has also been generated from the corresponding \( \text{cis-bicyclo[3.1.0]} \) hexan-3-ol in protic acid-free \( \text{Sbf}_5–\text{SO}_2\text{ClF} \) solution. The observed NMR spectral data agree very well with the \( \text{C}_3v \) symmetry of the ion \( \text{610} \). The \( ^{13}\text{C} \) NMR shifts are highly shielded for the three equivalent five-coordinate carbons (\( \delta^{13}\text{C} \) 4.9 with a \( ^{13}\text{C}–\text{H} \) coupling constant of 195.4 Hz), which is indicative of the nonclassical nature of the ion. Attempts to prepare methyl- and aryl-substituted trishomoencyclopropenyl cations were, however, unsuccessful, which is consistent with Jorgensen’s calculations.
The ethano-bridged analog 611 was also prepared from the 8-chloroticyclo[3.2.1.0^2.4]octane precursor. Ion 611 closely resembles the trishomoaromatic ion 610 in its spectral properties.

Another interesting trishomoaromatic system which has C\textsubscript{3v} symmetry is the 9-pentacyclo[4.3.0.0^2.8^2.0^5.7]nonylnyon cation 612 prepared by Coates and Fretz. Ion 612 has been thoroughly investigated in solvolysis. A rate enhancement of 10\textsuperscript{10} to 10\textsuperscript{12} compared with ordinary systems uncovered its highly delocalized nature (strain relief is not the reason for the degenerate rearrangement). Also, analysis of remote and proximate substituent effects upon ionization and application of the tool of increasing electron demand fully reinforced its nonclassical nature. A deuterium labeling study also confirms this conclusion.

Olah, Rasul, and Prakash have recalculated the trishomocyclopropenium ion 610 and calculated the structure of the hitherto unknown 1,3-dehydro-5-adamantyl cation 613 [DFT/IGLO method]. The B3LYP/6-31G* optimized geometry of cation 610 agrees well with that of the \textit{ab initio} structure (MP2/6-31G*) reported previously. Both ions have C\textsubscript{3v} symmetry, and the relevant C(1)–C(3) bond distance of ion 613 is only slightly longer than that of ion 610 (1.911 Å versus 1.859 Å), which indicates similar trishomoaromatic stabilization. The p orbitals of the three bridgehead sp\textsuperscript{2} carbon atoms [C(1), C(3), C(5)] of cation 613 overlap, involving two electrons. The C(1)–C(8) and C(8)–C(7) bond lengths differ only slightly from those of adamantane. This shows extensive delocalization of the positive charge among the sp\textsuperscript{2}-type C(1), C(3), and C(5) carbons without additional C–C hyperconjugation. The isodesmic reaction of the adamantyl cation and 1,3-dehydro-5-adamantane yields 613 and adamantane in an exothermic reaction (−20.0 kcal mol\textsuperscript{−1}). This is again indicative of significant stabilization due to trishomoaromatic interaction.

Recent computational studies gave conflicting results with respect to the nonclassical nature of the trishomocyclopropenium ion. According to the study of Werstiuk and Wang [B3PW91/6-311G(d,p) and MP4(SDQ)/6-311G(d,p) levels of calculations], the ion does not have pentacoordinate carbons, although it is stabilized by σ, σ-bond homoconjugation. Molecular properties calculated by Cremer and co-workers [HF and MP2/6-31G(d) level], in contrast, indicate a nonclassical structure with two-electron delocalization in the cycle as first predicted by Winstead.

3.5.3.4. Three-Dimensional Homoaromaticity. Schleyer and co-workers generated and observed the intriguing 1,3-dehydro-5,7-adamantanediyl dication 614 of T\textsubscript{d} symmetry with four-center two-electron bonding corresponding to a three-dimensional homoaromaticity [Eq. (3.147)]. In this system the p-orbitals of the four bridgehead carbon atoms overlap inward in the cage in a tetrahedral fashion. The chemical shifts of the bridgehead and the CH\textsubscript{2} carbons (δ\textsuperscript{13}C 6.6 and 35.6,
respectively), the unusual single sharp proton chemical shift ($^1H 3.8$), and the strong deformation (C–CH$_2$–C bond angle = 87.3°) predicted by calculations (3-21G ab initio geometry) are indicative of the nonclassical structure of ion 614. Population analysis at various levels (MNDO, MINDO/3, STO-3G, 3-21G) showed that the positive charge resides not only on the bridgehead carbons but also on all 12 hydrogens and the methylene carbons are neutral. The three-dimensional homoaromatic character of ion 614 has been further confirmed by more recent high-level theoretical studies by Chan and Arnold$^{1074}$ (ab initio HF/6-31G* level), Prakash et al.$^{1075}$ (B3LYP/6-31G*), and Schleyer and co-workers$^{1076}$ (B3LYP/6-31G*).

614

3.5.4. Pyramidal Cations

3.5.4.1. (CH)$_5^+$-Type Cations. The close relationship between carbocations and boranes led Williams$^{1077}$ to suggest the square-pyramidal structure 615 for the (CH)$_5^+$ cation based on the square pyramidal structure of pentaborane. Stohrer and Hoffmann$^{1078}$ subsequently came to the same conclusion concerning the preferred square-pyramidal structure for the (CH)$_5^+$ cation using extended Hückel MO calculations.

Cation 615 with $C_{4v}$ symmetry can be viewed$^{1078}$ as square cyclobutadiene capped by CH$^+$. Since then, several calculations of (CH)$_5^+$ at more sophisticated levels have appeared.$^{905,1079–1083}$ The MINDO/3 method$^{1084}$ indicated that the pyramidal cation 615 is less stable by 14.4 kcal mol$^{-1}$ compared with the isomeric singlet cyclopentadienyl cations 616 and 617. The triplet ion 618 of $D_{5h}$ symmetry was found to be only 1.6 kcal mol$^{-1}$ more stable than the singlet ions. The triplet ion 618 has been prepared$^{1085}$ by molecular beam codeposition of 1-bromocyclopentadiene with SbF$_5$ at 78 K and was characterized by ESR spectroscopy.

The fifth isomer, the vinylcyclopropenyl cation 619, has been suggested by Zerner and co-workers$^{1086}$ to be the most stable of the isomeric (CH)$_5^+$ cations (MP2/6-31G**/6-31G* level). Subsequent high-level ab initio calculations (G2 level of theory)$^{1087}$ however, found almost identical energies for 618 and 619. Indeed, recent ab initio [MP2(full)/6-31G*] and force-field calculations have shown$^{1088}$ that 618 is lower in energy than 619 by 1.2 kcal mol$^{-1}$. This study also showed$^{1088}$ that of the parent singlet cyclopentadienyl cations the allylic structure 616 is slightly favored over
the localized cyclopentadienyl cation structure 617. The stability of the alkyl-substituted analogs, however, depends on the substitution patterns.

Lambert et al.\textsuperscript{1089} have claimed in a recent report the synthesis of the stable pentamethylcyclopentadienyl cation 621 by hydride transfer from pentamethylcyclopentadiene (620) with the trityl cation [Eq. (3.148)]. The NMR data, however, are characteristic of allyl cations, and it became obvious that the product is not cation 621 but the known trans-1,2,3,4,5-pentamethyl-1-cyclopentenyl allylic cation 622.\textsuperscript{1090–1094} Particularly revealing is the C(4)–C(5) bond length (1.51 Å) of the reported X-ray structure, which is too long for a carbon–carbon double bond. The calculated bond distance for 621 is 1.36 Å and 1.351 Å (reported by Lambert et al.\textsuperscript{1089} and by Müller,\textsuperscript{1091} respectively). The carbon–carbon single bond lengths for cation 622 observed experimentally (1.517 Å\textsuperscript{1093}) are practically identical with computed bond lengths (1.545 Å\textsuperscript{1091} and 1.535 Å\textsuperscript{1093}). In the synthesis performed by Lambert, cation 622 was most probably formed by protonation of some acid impurity. In fact, ion 622 could be synthesized by reacting 620 with triflic acid.\textsuperscript{1090} Consequently, cation 621 remains elusive.

\[

\end{align*}
\]

(3.148)

Although experimental work on the parent square pyramidal (CH)\textsubscript{5}\textsuperscript{+} ion has not been reported, a dimethyl-substituted derivative 623 of the pyramidal ion 615, however, has been prepared by Masamune et al.\textsuperscript{1095,1096} and studied by \textsuperscript{1}H and \textsuperscript{13}C NMR spectroscopy. Ionization of the dimethylhomotetrahedranol under superacidic conditions gave the pyramidal ion 623 [Eq. (3.149)]. The alternative singlet cyclopentadienyl structures (616 and 617) for the species was eliminated based on \textsuperscript{1}H and \textsuperscript{13}C NMR data. The highly shielded C(5) carbon chemical shift (δ\textsuperscript{13}C = -23.0) supports the structure 623 over a set of rapidly equilibrating structures such as 624a and 624b. The quenching of ion 623 at low temperature affords cyclopentenes.

\[
\begin{align*}
\text{a} & \quad \text{b} \\
\text{624} & \quad \text{etc.}
\end{align*}
\]
Attempts have been made to observe\textsuperscript{1084} the assumed interconversion of \textbf{625} to \textbf{626} in fluorenlyl cations. Such intramolecular interconversion through the capped pyramidal ion \textbf{627} was not observed [Eq. (3.150)]. MINDO/3 calculations\textsuperscript{1084} on the isomeric structures of cyclopentadienyl, indenyl, and fluorenlyl cations indicated strongly decreasing relative stabilities of pyramidal forms due to bezannulation.

\[
\begin{align*}
\textbf{625} & \rightleftharpoons \textbf{627} & \textbf{626} \\
\end{align*}
\]

Equation (3.150)

Insertion of a methylene group into the four-membered ring of the pyramidal (CH)\textsubscript{5}\textsuperscript{+} cation \textbf{615} would give rise to the homo derivative \textbf{628}. As discussed earlier,\textsuperscript{41,1037–1041} hexamethylbicyclo[2.1.1]hexenyl cation is best represented as a bishomocyclopropenyl cation \textbf{586} and not pyramidal-type ion \textbf{629}.

\[
\begin{align*}
\textbf{628} & \quad \textbf{629} \\
\end{align*}
\]

The trishomocyclopropenyl cation \textbf{630} has been investigated by both solvolytic\textsuperscript{1097–1100} and stable ion studies\textsuperscript{1096} The obtained \textsuperscript{1}H and \textsuperscript{13}C NMR data could be explained with the intermediacy of the bishomo square pyramidal ion \textbf{631}, although no conclusive distinction could be made between rapidly equilibrating systems of \textbf{630} and \textbf{631} structures. However, the ion \textbf{631} of \textit{C}_{2v} symmetry was preferred based on related MINDO/2 calculations.\textsuperscript{1101} Subsequent high-level computational studies have confirmed,\textsuperscript{1102} that cation \textbf{630} is not an energy minimum on the potential energy surface and converges upon optimization into structure \textbf{631} (MP2/cc-pVTZ level). Recent \textit{ab initio} calculations [GIAO-CCSD(T) method]\textsuperscript{1103} have arrived at the same conclusion. The classical structure \textbf{632} (\textit{C}_{s} symmetry), a dicyclopropylcarbinyll cation, was also shown to be energy minimum on the potential energy surface being 5.1 kcal mol\textsuperscript{-1} less stable than cation \textbf{631}. The calculated \textsuperscript{13}C NMR chemical shifts agree very well with the experimental values.
The other two substituted bishomo-(CH)$_5^+$ cations that have been investigated in superacid media are the octamethylated ion 633 and its methano-bridged analog 634. The observed $^{13}$C NMR data of both ions$^{1097,1104-1106}$ are consistent with their highly symmetrical structures 633 and 634, but the data could also be explained with degenerate rapidly equilibrating systems of lesser symmetry. Hart and Willer$^{1106}$ determined the apical $^{13}$C--$^1$H coupling constant of ion 633 ($J_{C-H} = 220$ Hz), which is consistent with the single pyramidal structure 633 with nearly $sp$ hybridization of the apical carbon atom. Surprisingly, the bishomoaromatic 7-norbornenyl cation 581 has nearly identical $^{13}$C--$^1$H coupling constant as the ion 633 at the C(7) carbon.$^{1011}$ Recently, rearrangements involving C$_8$H$_8$F$^+$ cation have been studied.$^{1107}$

Both the bishomo square pyramidal structure 634 of $C_{2v}$ symmetry and the trishomocyclopropenium-type structure 635a/635b ($C_s$ symmetry) were found to be minima on the potential energy surface of C$_8$H$_9^+$, but they are almost isoenergetic: Cation 635 is higher in energy than ion 634 only by 0.2 kcal mol$^{-1}$ [MP4(SDQ)/6-31G*/MP2/6-31G*+ZPE level$^{1102}$] or 0.7 kcal mol$^{-1}$ (MP2/cc-pVTZ/MP2/cc-pVTZ+ZPE level$^{1103}$). The observed spectrum of C$_8$H$_9^+$ could be reproduced quite well with a weighted average of the experimental and calculated NMR spectra. These observations indicate that an equilibrium mixture undergoing rapid exchange on the NMR time scale involving ion 634 and 635 (in a 1:2 ratio) can best represent the structure of C$_8$H$_9^+$.

### 3.5.4.2. (CH)$_6^{2+}$-Type Dications

The first known representative of the (CH)$_6^{2+}$-type hexacoordinate pyramidal dications is Hogeveen’s hexamethyl cation 437.$^{41,789,1108}$ This dication 437 can be prepared from a variety of precursors in superacidic media (HSO$_3$F, HSO$_3$F–SbF$_5$) at low temperature (Scheme 3.28).

The observed fivefold symmetry in the $^1$H and $^{13}$C NMR spectra even at very low temperature ($-150^\circ$C) with no line broadening leaves only two alternatives for the structure of the dication: the nonclassical fivefold symmetrical, static structure 437 or
a set of rapidly equilibrating degenerate dications 636 (Scheme 3.29) with an activation energy barrier of less than 5 kcal mol$^{-1}$.

The $^1$H and $^{13}$C NMR data, the rates of deuterium exchange, the rate of carbonylation, and the thermal stability of 437 provide strong evidence for the nonclassical
nature of this carbodication. However, the structure can be also be considered in terms of the rapidly equilibrating set of structures \(636\) that have only one plane of symmetry during the degenerate process; the apical C-atom describes a circle.

Although the observed \(^1\)H and \(^{13}\)C NMR data strongly support the bridged nature of the ion \(437\), further definitive evidence comes from isotope perturbation studies.\(^{1109}\) Very little isotopic perturbation (the degeneracy is not lifted due to CD\(_3\) substitution) on the basal carbon signal is observed in the \(^{13}\)C NMR spectrum of the dication \([\text{C}_6(\text{CH}_3)_4(\text{CD}_3)_2]^{2+}\), indicating that the ion is symmetrically bridged. Other supporting evidence comes from a comparison of the \(^{13}\)C and \(^{11}\)B NMR shifts of the isoelectronic borane \(\text{B}_6\text{H}_{10} \ 637\). Williams and Field have shown\(^{936}\) that the \(^{13}\)C NMR chemical shifts of a series of nonclassical cations may be compared with the \(^{11}\)B NMR chemical shifts of the isoelectronic polyhedral polyboranes.

Hogeveen, Heldeweg, and co-workers\(^{1110,1111}\) also prepared the ethyl- and isopropyl-substituted analogs \(638a–638d\) of the dipositive ion (CH\(_6\))\(^2+\) and their bridged structures have been confirmed by \(^1\)H and \(^{13}\)C NMR spectroscopic and quenching studies.

\[
\begin{align*}
637 \quad & \quad 638 \\
a & R = \text{Me}, R' = \text{Et} \\
b & R = \text{Me}, R' = \text{isoPr} \\
c & R = R' = \text{Et} \\
d & R = R' = \text{isoPr}
\end{align*}
\]

Lambert et al.\(^{1112}\) have performed a study to learn if the \(\text{C}_5\text{SiMe}_7^+\) cation \(639\), the monosila analog of the \(\text{C}_6\text{Me}_7^+\) cation, can be accessed [Eq. (3.151)]. Cation \(639\) is related to Hogeveen’s hexamethyl cation \(437\). Either a static structure with fivefold symmetry or a dynamic structure with the dimethylsilyl group equilibrating rapidly among positions is in agreement with the \(^1\)H and \(^{13}\)C NMR spectra (a single resonance for the ring methyl groups and a single resonance for the methyl groups on silicon). DFT calculations [B3LYP/6-31G(d,p) level] indicated the unsymmetrical silabicyclo[3.1.0]hexenyl structure \(640\) to be the global minimum. GIAO calculated and experimentally observed \(^1\)H, \(^{13}\)C, and \(^{29}\)Si chemical shift values are in good agreement.

4.1. INTRODUCTION

This chapter deals with cations generated in superacid media wherein the positive charge is located on an atom other than carbon. The heteroatoms include oxygen, sulfur, selenium, tellurium, nitrogen, chlorine, bromine, iodine, hydrogen, xenon, and krypton. This discussion is divided for convenience into the following sections: (i) higher valency onium ions such as oxonium, sulfonium, selenonium, telluronium, halonium, diazonium, and other species; (ii) enium ions of boron (borenium) and aluminum (alumenium), silicon (silicenium), germanium (germenium), tin (stannylium), and lead (plumbiylium); nitrogen (nitronium), phosphorus (phosphenium), arsenic (arsenium), and antimony (stibenium); (iii) homo- and heteropolyatomic cations of halogens (interhalogen cations), polyhomoatomic cations of oxygen, sulfur, selenium, and tellurium, and other polyatomic and polyheteroatomic cations; (iv) cations of group 6–12 elements; and (v) miscellaneous cations of hydrogen, xenon, and krypton.

4.2. ONIUM IONS

4.2.1. Oxonium Ions

The synthesis, structural characteristics, and chemistry of oxonium ions have been extensively investigated and reviewed.1

4.2.1.1. Hydronium Ion (H₃O⁺). The hydronium ion (H₃O⁺, 1) is the parent of saturated oxonium ions. It was first postulated in 1907² and gained wider acceptance with the acid–base theory of Brønsted³ and Lowry.⁴ The lifetime of 1 in aqueous solution has been estimated to be about 10 times longer than the time scale of molecular vibrations.⁵,⁶ The hydronium ion 1 has been studied in the gas phase as well as in solution (IR,⁷–¹⁰ Raman,¹¹,¹² NMR,¹³–¹⁶ MS,¹⁷,¹⁸ and neutron diffraction¹⁹,²⁰).

---

Copyright © 2009 John Wiley & Sons, Inc.
In fact, Christe et al.\textsuperscript{21,22} have isolated hydronium salts with a variety of counterions such as SbF\textsubscript{6}\textsuperscript{−}, AsF\textsubscript{6}\textsuperscript{−}, and BF\textsubscript{4}\textsuperscript{−}. Complete vibrational\textsuperscript{7–10} and neutron diffraction studies\textsuperscript{19,20} support the pyramidal nature of the hydronium ion I. Extensive evidence for the long-lived hydronium ion has been obtained in superacid solution.\textsuperscript{13,14,16} In the mass spectrum, evidence has also been obtained for water-solvated hydronium ions such as H\textsubscript{2}O\textsubscript{2}\textsuperscript{+} and H\textsubscript{2}O\textsubscript{3}\textsuperscript{+}. Isolation and X-ray crystal structure characterization of H\textsubscript{3}O\textsuperscript{+}SbF\textsubscript{6}\textsuperscript{−},\textsuperscript{22,23} H\textsubscript{3}O\textsuperscript{+}Sb\textsubscript{2}F\textsubscript{11}\textsuperscript{−},\textsuperscript{24} H\textsubscript{3}O\textsuperscript{+}SbCl\textsubscript{6}\textsuperscript{−} stabilized by acetonitrile,\textsuperscript{25} and H\textsubscript{3}O\textsubscript{2}\textsuperscript{+}SbX\textsubscript{6}\textsuperscript{−} salts (X = F, Cl)\textsuperscript{26,27} have been reported.

The $^1$H NMR spectrum of H\textsubscript{3}O\textsuperscript{+} (1) in superacids such as HSO\textsubscript{3}F–SbF\textsubscript{5} (Magic Acid) and HF–SbF\textsubscript{5} is observed at $\delta$ $^1$H 11.0 (from trimethylsilane).\textsuperscript{13,14,16} $^{17}$O NMR spectroscopic studies\textsuperscript{28,29} in HF–SbF\textsubscript{5} with $^{17}$O-enriched hydronium ion have indicated strong $^{17}$O–$^1$H coupling (Figure 4.1). In the proton-coupled spectrum, a quartet is observed at $\delta^{17}$O 9 ± 0.2 (with reference to SO\textsubscript{2} at 505 ppm) with $J_{^{17}O-^1H} = 106 \pm 1.5$ Hz.

Mateescu and Benedikt\textsuperscript{28} suggested that I is planar and not pyramidal, on the basis of a 33% increase in $^{17}$O–$^1$H coupling constant upon going from H\textsubscript{2}O to H\textsubscript{3}O\textsuperscript{+}. They assumed a linear relationship between $J_{^{17}O-^1H}$ and the hybridization state of oxygen. Symons\textsuperscript{30} subsequently showed that the assumed $sp^3$ hybridization for H\textsubscript{2}O by Mateescu and Benedikt was not true (H\textsubscript{2}O has a bond angle of 104.5°\textsuperscript{31}). Redoing the calculation, Symons showed that the hydronium ion I is pyramidal with an H–O–H bond angle of 111.3°. Similar conclusions have been reached on the basis of quantum mechanical calculations.\textsuperscript{32}

Figure 4.1. $^{17}$O NMR spectrum of H\textsubscript{3}O\textsuperscript{+} (1) in HSO\textsubscript{3}F–SbF\textsubscript{5}–SO\textsubscript{2} at $-20°C$. (a) Proton decoupled, (b) proton coupled.
The hydronium ion forms clusters with electron pair donor molecules such as water\(^{33}\) and crown ethers\(^{34-36}\). Since the pioneering work of Kebarle\(^{37}\) on \(\text{H}_3\text{O}^+.(\text{H}_2\text{O})_n\) clusters by mass spectrometry, their structures and energetics have been thoroughly studied\(^{33,38,39}\). Two main structural models have emerged. Eigen proposed\(^{40}\) the formation of a \(\text{H}_3\text{O}_4^+\) complex in which the \(\text{H}_3\text{O}^+\) core is strongly hydrogen-bonded to three \(\text{H}_2\text{O}\) molecules. Zundel,\(^{41}\) in turn, suggested the existence of a \(\text{H}_5\text{O}_2^+\) complex with the proton being shared between two \(\text{H}_2\text{O}\) molecules. \(\text{H}_3\text{O}^+.(\text{H}_2\text{O})_{20}\) is considered a magic number cluster due to its enhanced stability originating from the closed cage structure. This cluster has been shown to form a pentagonal dodecahedral cage with 11 non-hydrogen-bonded hydrogens extending out from the ion\(^{42,43}\). Recent theoretical studies such as Car–Parrinello molecular dynamics indicate\(^{44}\) that Eigen and Zundel structures may be considered as limiting, equilibrating cases. By the use of a novel approach (multiconfigurational time-dependent Hartree), Meyer and co-workers\(^{45}\) were able to simulate the experimental gas-phase spectrum of \(\text{H}_3\text{O}_2^+\) with surprising accuracy.

The oxonium dication \(\text{H}_4\text{O}_2^+\), which may play a role in superacid-catalyzed H–D exchange reactions via an associative mechanism, has been studied theoretically. The tetrahedral symmetry structure was found to be a minimum (HF/6-31G* level).\(^{46}\) Treatment with GAUSSIAN-2 method\(^{47}\) gives a dissociation energy of \(-61.9\) kcal mol\(^{-1}\) and a kinetic barrier of \(38.2\) kcal mol\(^{-1}\) for deprotonation. Practically the same values (\(-61.3\) and \(38.1\) kcal mol\(^{-1}\)) have been computed at the QCISD(T)/6-311G (2df,2p)/MP2(full)/TZP + ZPE/MP2(full)/6-31G** level.\(^{48}\)

### 4.2.1.2. Primary Oxonium Ions [ROH\(^2+\)].

It has been shown\(^{49}\) that methyl and ethyl alcohol in sulfuric acid give stable solutions of the corresponding alkyl hydrogen sulfates 2 [Eq. (4.1)]. Many other alcohols show similar initial behavior, but the solutions are not stable at room temperature.

\[
\text{R} = \text{OH} + 2\text{H}_2\text{SO}_4 \rightarrow \text{R} = \text{OSO}_3\text{H} + \text{H}_3\text{O}^+ + \text{HSO}_4^- \tag{4.1}
\]

The first direct NMR spectroscopic evidence for the existence of primary alkyl oxonium ions (protonated alcohols) in superacid solutions was found in 1961 by MacLean and Mackor.\(^{50}\) The NMR spectrum of ethanol in HF–BF\(_3\) solution at \(-70^\circ\text{C}\) gave a well-resolved triplet at about \(\delta^1\text{H} 9.90\) for the protons on oxygen coupled to the methylene protons. In HSO\(_3\)F this fine structure is not observed, even at \(-95^\circ\text{C}\), due to the fast proton exchange.\(^{51}\)

The NMR spectra of a series of aliphatic alcohols have been investigated in the stronger acid system HSO\(_3\)F–SbF\(_3\) using sulfur dioxide as diluent\(^{52,53}\) [Eq. (4.2)]. Methyl, ethyl, \(n\)-propyl, isopropyl, \(n\)-butyl, isobutyl, \(sec\)-butyl, \(n\)-amyl, neopentyl, \(n\)-hexyl, and neo-hexyl alcohol all give well-resolved NMR spectra at \(-60^\circ\text{C}\), under these conditions (Figure 4.2).

\[
\text{R} = \text{OH} \xrightarrow{\text{HSO}_3\text{F}–\text{SbF}_3–\text{SO}_2 \ (-60^\circ\text{C})} \text{R} = \text{O}^+\text{H}_2 \tag{4.2}
\]
The strength of the HSO$_3$F–SbF$_5$ acid system is reflected by the fact that even at 25°C, solutions of primary alcohols show fine structure for the proton on oxygen (Figure 4.2). This indicates that at this relatively high temperature the exchange rate is still slow on the NMR time scale. In $^1$H NMR, the OH$^+$ protons of the primary alcohols appear at lower field ($\delta^{1}H$ 9.3–9.5) than the isomeric secondary alcohols ($\delta^{1}H$ 9.1). This is due to a different charge distribution, as confirmed by the C(1) protons of the primary alcohols appearing at higher field ($\delta^{1}H$ 5.0–4.7) compared with the C(1) methine proton of the secondary alcohols ($\delta^{1}H$ 5.4 and 5.5). The $^{17}$O chemical shift of protonated methyl alcohol is deshielded by approximately 25 ppm from the neutral methyl alcohol. The $^{17}$O–$^1$H coupling constant of 107.6 Hz is similar in magnitude to that of the parent oxonium ion H$_3$O$^+$.1

Minkwitz and Schneider$^{54}$ have been able to obtain protonated methanol in the form of hexafluorometalate salts (MeOH$_2^+MF_6^-$, M = As, Sb), and these were characterized by X-ray diffraction. Protonated propanol and proton-bound dimers of methanol, ethanol, and propanol with the proton shared between two alcohol molecules (5) have also been characterized by infrared multiphoton dissociation.
spectroscopy. The synthesis and X-ray crystal structure of the oxonium salt \([\text{H(OEt}_2]^+\text{(C}_6\text{F}_5)_4\text{B}^-]\) have recently been reported. Unfortunately, the proton could not be located. Thin molecular films of ethanol and tert-butyl alcohol on Ru(001) surface have been prepared and reacted with HBr. Only protonated ethanol \(\text{EtOH}_2^+\) was detected on the ethanol surface by \(\text{Cs}^+\) reactive ion scattering and low-energy sputtering. In contrast, on the tert-butyl alcohol surface, both protonated alcohol \(\text{Me}_3\text{COH}_2^+\) and tert-butyl cation, \(\text{Me}_3\text{C}^+\) were formed.

![Diagram](image)

Aliphatic glycols in HSO\(_3\)F–SbF\(_5–\)SO\(_2\) solution give diprotonated species at low temperatures. In diprotonated diols, the protons on oxygen are found at lower fields than in protonated alcohols reflecting the presence of two positive charges. This is especially true for ethylene glycol \((\delta^1\text{H} 11.2)\), where the positive charges are adjacent. As the separation of the positive charges becomes greater with increasing chain length, the chemical shift of the protons on oxygen of protonated diols approaches that of protonated alcohols.

The reactivity of protonated alcohols and protonated diols in strong acids has been studied by NMR spectroscopy. Protonated methyl alcohol shows surprising stability in HSO\(_3\)F–SbF\(_5\) and can be heated to 50°C without significant decomposition, although surprising condensation to tert-butyl cation was occasionally observed. Protonated ethyl alcohol is somewhat less stable and begins to decompose at 30°C. The cleavage of protonated \(n\)-propyl alcohol has been followed in the temperature range 5–25°C, giving a mixture of tert-butyl and tert-hexyl cations [Eq. (4.3)].

\[
\text{CH}_3\text{CH}_2\text{CH}_2\text{OH}_2 + \text{HSO}_3\text{F}–\text{SbF}_5 \xrightarrow{5–25^\circ\text{C}} (\text{CH}_3)_3\text{C}^+ + (\text{CH}_3)_2\text{C}_\text{CH}(\text{CH}_3)_2^+ + \text{H}_2\text{O}^+ \quad (4.3)
\]

Higher protonated alcohols cleave to stable tertiary alkyl cations. For protonated primary and secondary alcohols, the initially formed primary and secondary carbocations rapidly rearrange to the more stable tertiary carbenium ions under the conditions of the reaction. For example, protonated \(n\)-butyl alcohol cleaves to \(n\)-butyl cation which rapidly rearranges to tert-butyl cation \((k_2 >> k_1)\) [Eq. (4.4)].

\[
\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{OH}_2 \xrightarrow{k_1\text{H}_2\text{O}} [\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2]^+ \xrightarrow{k_2} (\text{CH}_3)_3\text{C}^+ \quad (4.4)
\]

The cleavage of carbocations, shown to be first order, is enhanced by branching of the chain: Protonated 1-pentanol is stable up to 0°C, isopentyl alcohol is stable up to
−30°C, and neopentyl alcohol cleaves at −50°C. The stability of the protonated primary alcohols also decreases as the chain length is increased.

When the HSO₃F−SbF₅−SO₂ solutions of diprotonated glycols are allowed to warm up,⁵⁸ pinacolone rearrangements, formation of allylic carbenium ions, and cyclization reactions of diprotonated glycols can be directly observed by NMR spectroscopy. Diprotonated ethylene glycol 8 rearranges to protonated acetaldehyde in about 24 h at room temperature [Eq. (4.5)]. Protonated 1,2-propanediol undergoes a pinacolone rearrangement to protonated propionaldehyde, probably through the initial cleavage of water from the secondary position. Diprotonated 2,3-butanediol 9 rearranges to protonated ethyl methyl ketone either through direct hydride shift or through a bridged intermediate (Scheme 4.1).

Diprotonated 2,4-pentanediol 10 loses water and rearranges to form 1,3-dimethyl allyl cation [Eq. (4.6)]. Diprotonated 2,5-hexanediol 11, above −30°C, rearranges to a mixture of protonated cis- and trans-2,5-dimethyltetrahydrofurans [Eq. (4.7)]. This would seem to indicate that there is a significant amount of the monoprotonated form present or that the carbocation formed can easily lose a proton before ring formation occurs.
According to protonation thermochemistry of simple α,ω-diols (1,2-ethanediol, 1,3-propanediol, 1,4-butanediol), the diols show enhanced proton affinities in the gas phase compared with primary alcohols attributed to the formation of a strong intramolecular hydrogen bond.\(^{59,60}\)

In the case of phenols, either C- or O-protonated ion \(12\) or \(13\) are formed, depending upon the acidity of the medium. In relatively weak acid medium such as H\(_2\)SO\(_4\), only O-protonation is observed. However, in HSO\(_3\)F only the C-protonated species is formed.\(^{62}\) In a much stronger acid system such as HSO\(_3\)F–SbF\(_5\) (Magic Acid), both C- or O-protonated dication \(14\) can be observed. Both the C- and O-protonated ions were shown to exist in the gas phase by IR photodissociation spectroscopy.\(^{63}\)

In addition to the direct protonation of alcohols or phenols, haloalkyloxonium ions can be generated from carbonyl compounds. Olah et al.\(^{64}\) prepared halomethyloxonium ions XCH\(_2\)OH\(^+\) (X = F, Cl) by the protonation of formaldehyde with HF–SbF\(_5\) or using a mixture of HCl and HSO\(_3\)F–SbF\(_5–SO_2\). Minkwitz and Reinemann\(^{65}\) reacted hexafluoroacetone with HF–SbF\(_5\) to prepare an analogous primary oxonium ion [Eq. (4.8)].

Christe et al.\(^{66}\) have recently reported an easy access to trifluoromethanol (CF\(_3\)OH) by reacting carbonyl difluoride with anhydrous HF. In fact, trifluoromethanol exists in equilibrium with CF\(_3\)O and HF. It was found during their study that CF\(_3\)OH is not protonated by HF; however, it could be converted to trifluoromethyloxonium M\(\text{F}_6\)\(^-\) salts (M = Sb, As).
The synthesis under stable ion conditions and characterization by $^1$H, $^{13}$C, and $^{29}$Si NMR spectroscopy of the [(trimethylsilyl)methyl]oxonium ion 15 have been reported by Olah et al. Protonation of the corresponding alcohol with Magic Acid gives ion 15, which is stable and can be isolated at room temperature [Eq. (4.9)].

$$\text{Me}_3\text{SiCH}_2-\text{OH} \xrightarrow{\text{HSO}_3\text{F-SbF}_5-\text{SO}_2-\text{SO}_2\text{ClF}} \text{Me}_3\text{SiCH}_2-O+$$  

(4.9)

Silyloxonium ions (protonated silanols) 16 have also been prepared, and the crystal structure of the tert-butyl derivative 16c as the Br$_6$CB$_{11}$H$_6^-$ salt has been reported. The most notable features of ion 16c are the flattening of the silicon center (average C–Si–C angle = 116.0°) and the long Si–O bond (1.779 Å). The Si–O bond distance of the corresponding methyl derivative 16a (1.929 Å) calculated by Olah et al. (B3LYP/6-31G* level) is only 0.1 Å longer than that found in 16c. The IGLO II' calculated $^{29}$Si NMR chemical shift of 16a is considerably deshielded from that of the neutral precursor Me$_3$SiOH ($d^{29}$Si 101.9 versus 15.1). In contrast, the $^{29}$Si NMR chemical resonance of tert-butyl derivative 16c is even shielded compared with that of 16a ($d^{29}$Si 46.7).

In protonated (amidomethyl)dimethylsilanols, such as 17, the Si–O(1) distance is even longer (1.9114 Å) due to the additional Si–O(2) interaction. According to AIM calculations, the O–Si–O moiety is a 3c–4e bond and the positive charge is largely localized on silicon. The Si–O(1) bond length (1.9604 Å) is similar to that of Si–O(2) and the sum of the three C–Si–C bond angles is 359.9°. These data indicate that the structure may be described as an intermediate of aqueous hydrolysis of silanes.

Monofluorooxonium hexafluorometalates have been synthesized by Minkwitz and co-workers by fluorinating H$_2$O with XeF$^+$MF$_6^-$ [Eq. (4.10)]. The salts can be stored at room temperature for 2 h without decomposition.

$$\text{XeF}^+\text{MF}_6^- + \text{H}_2\text{O} \xrightarrow{\text{HF} \text{M} = \text{As, Sb}} \text{F-O}^+\text{MF}_6^- \xrightarrow{\Delta} \text{HF} + \text{HOF} + \text{MF}_5$$  

(4.10)
Superelectrophilic fluorooxonium dications \( \text{FOH}_3^{2+} \) and \( \text{F}_2\text{OH}_2^{2+} \) derived from \( \text{HOF} \) and \( \text{F}_2\text{O} \), respectively, have been studied theoretically [QCISD(T)/6-311G**].\(^{74}\) Both the \( O,O \)-diprotonated structure 18 and the \( O,F \)-diprotonated structure 19 were found to be energy minima with the oxonium dication 18 being 14.9 kcal mol\(^{-1}\) less stable than the oxonium–fluoronium dication 19. The \( O,O \)-diprotonated dication 20, in turn, is the only minimum on the potential energy surface for the \( \text{F}_2\text{OH}_2^{2+} \) system. All of these species have substantial kinetic barriers for deprotonation to the corresponding monocations.

![Diagram of structures 18, 19, and 20](image)

### 4.2.1.3. Secondary Oxonium Ions [\( \text{RR}^+\text{OH}^- \)]

\(^1\)H NMR and IR investigation\(^{75}\) of protonated ether salts (hexachloroantimonates) in dichloromethane solutions showed the formation of both (a) dialkyl oxonium ions in which the proton is bound to only one oxygen (21) and (b) bidentate complexes in which the proton is shared between two ether molecules (22). Structural analysis of such a bidentate complex of diethyl ether with a complex anion shows a broad \( \text{H}^+ \) resonance at \( \delta^1\text{H} 16.3 \) and unequal \( \text{O–H} \) bond distances (1.39 and 1.11 Å).\(^{76}\)

![Diagram of structures 21 and 22](image)

In the \( ^1\)H NMR, the proton on oxygen showed up as a singlet around \( \delta^1\text{H} 7–9 \) with no coupling with adjacent alkyl protons, indicating rapid proton exchange under the reaction conditions. Investigations using the superacid system \( \text{HSO}_3\text{F}–\text{SbF}_5–\text{SO}_2 \) at low temperatures lead to comparable values for the chemical shift to the proton on oxygen for a variety of aliphatic ethers at \( \delta^1\text{H} 7.88–9.03 \). Because of the stronger acid system and the low temperature, however, the exchange rate is slowed down sufficiently so that the expected splitting of the proton resonance on oxygen by the adjacent hydrogens is observed\(^{77} \) (Figure 4.3). Diprotonated dimethyl ether \( \text{Me}_2\text{OH}_2^{2+} \) has been computed (MP2/6-31G*/MP2/6-31G* level) and found to be a stable \( O,O \)-diprotonated isomer.\(^{47}\)

The cleavage of protonated ethers in strong acid systems has not been studied extensively. Kinetic investigation of the cleavage of ethers in 99.6% sulfuric acid using cryoscopic methods showed that cleavage takes place by unimolecular fission of the conjugated acid of the ether to form the most stable carbocation and an alcohol. The carbocation and alcohol formed rapidly unite with the hydrogen sulfate anion.
The overall rate in sulfuric acid, however, appears to be dependent upon the concentration of sulfur trioxide. To rationalize these observations, the mechanism outlined in Scheme 4.2 has been proposed.\textsuperscript{78}

\begin{align*}
R-O-R' + H_2SO_4 &\rightleftharpoons R^+ + R'OSO_2OH \\
R^+ + SO_3 &\rightleftharpoons R^+ + R'OSO_2H \\
R^+ + HSO_4^- &\longrightarrow ROSO_2OH
\end{align*}

Scheme 4.2

In a solution of HSO$_3$F–SbF$_5$, protonated \textit{n}-butyl methyl ether 23 does not show any significant change, neither cleavage nor rapid exchange, as indicated by the NMR spectrum up to +40°C. Above +40°C, however, it cleaves and a sharp singlet appears at $\delta^1$H 4.0. This can be attributed to the rearrangement of the \textit{n}-butyl cation, formed in the cleavage, to \textit{tert}-butyl cation [Eq. (4.11)].

\begin{align*}
\text{CH}_3\text{OCH}_2\text{CH}_2\text{CH}_2\text{CH}_3 + H^+ &\rightarrow \text{CH}_3\text{O}_2\text{H} + [\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2]^+ \\
(4.11)
\end{align*}
Ethers in which one of the groups is secondary begin to show appreciable cleavage at $-30^\circ\text{C}$. Protonated sec-butyl methyl ether 24 cleaves cleanly at $-30^\circ\text{C}$ to protonated methanol and tert-butyl cation [Eq. (4.12)]. Ethers in which one of the alkyl groups is tertiary cleave rapidly even at $-70^\circ\text{C}$. 

$$\text{CH}_3\text{CH}_2\text{CHOCH}_3 + \text{H}^+ \xrightarrow{k_1} \text{CH}_3\text{OH} + \text{[CH}_3\text{CH}_2\text{CH}_3\text{]} \xrightarrow{k_2} \text{(CH}_3\text{)}_3\text{C}^+ \text{ (4.12)}$$

It was found possible to measure the kinetics of cleavage of protonated sec-butyl methyl ether 24 by following the disappearance of the methoxy doublet in the NMR spectrum with simultaneous formation of protonated methanol and tert-butyl cation. The cleavage shows pseudo-first-order kinetics. Presumably, the rate-determining step is the formation of sec-butyl cation followed by rapid rearrangement to the more stable tert-butyl cation ($k_2 \gg k_1$).

Olah and Szilagyi have studied the protonation of three-, four-, five-, and six-membered cyclic ethers in HSO$_3$F–SbF$_5$–SO$_2$ solution at $-60$ and $-78^\circ\text{C}$. The $^1\text{H}$ NMR spectra of ethylene oxide and propylene oxide showed a broad signal, which could be due to protonated oxirane moiety. No evidence of any long-lived intermediate was found for more highly substituted oxiranes at the temperature range studied. This, however, is not unexpected, considering the strained structures and that ring opening leads to more stable tertiary carbonium ions. In contrast, the homologous cyclic ethers of larger rings gave well-resolved spectra with negligible exchange rates.

Protonation and cleavage of cyclic ethers, particularly that of oxiranes, have been extensively studied by calculations. Protonated ethylene oxide and propylene oxide were found to be energy minima on the potential energy surface, being more stable than the corresponding carbenium ions. In contrast, benzene oxide and styrene oxide give carbenium ions as energy minima upon protonation. Protonation of propylene oxide can yield both syn and anti oxonium ions with the syn stereoisomer having marginally higher stability at all levels of theory (0.2 kcal mol$^{-1}$ at the MP2/6-31G* level). High-level ab initio calculations show that a concerted, asynchronous pathway exists between protonated propylene oxide and ring-opened product protonated propanal. The reaction shows a 20:1 preference for migration of the proton trans to the methyl group. AIM theory employed for a series of protonated oxacycloalkanes (CH$_2$)$_n$OH$^+$ ($n = 2$–6) indicates that the positive charge is partially concentrated on hydrogen. This led the authors to suggest that protonated ethers are better described by an O–H$^+$ structure.

Carlier et al. have carried out a comparative study of protonated 2,2-dimethyl-oxirane using a range of density functional methods. It was found that relative to CCSD, all methods except MP2 overestimated the C(2)–O bond length of protonated 2,2-dimethyloxirane by about 0.2 Å. The difficulty lies in the extremely weak C(2)–O bond, which is shown by the highly asymmetric charge distribution between the two ring carbons [Mulliken charges of C(2) and C(3) are +0.419 and −0.460, respectively]. Data for protonated oxiranes with more symmetrical charge distributions and cyclic
homologues with less ring strain (protonated 2,2-dimethyloxetane and 2,2-dimethyl-
oxolane) can be calculated by B3LYP with greater accuracy (deviations in bond lengths are +0.073 Å and +0.061 Å, respectively).

Olah et al. also prepared secondary [(trimethylsilyl)methyl]oxonium and trimethylsilyloxonium ions (25 and 26). 13C NMR characterization of the ions showed that the α- or β-trialkysilyl substituents induce little charge delocalization. The 29Si NMR chemical shift of the bistrimethylsilyl derivative 26 (R = Me3Si) calculated by Olah, Rasul, and Prakash (IGLO II') is considerably deshielded from that of the neutral precursor Me3SiOH (δ29Si 67.6 vs. 15.1). Secondary oxonium ions with halogen heteroatom ligands (27) were synthesized by Minkwitz and Konikowski. Proton resonances were found at δ1H 5.3 ppm (X = F) and 4.1 ppm (X = Cl), respectively.

\[
\begin{align*}
\text{Me}_3\text{SiCH}_2 & - \text{O}^+ \quad R = \text{Me}, \text{Me}_3\text{SiCH}_2 \\
\text{Me}_3\text{Si} & - \text{O}^+ \quad R = \text{Me}, \text{Me}_3\text{Si}, \text{Me}_3\text{SiCH}_2 \\
\text{Me}_3\text{Si} & - \text{O}^+ \\
\text{Me}_3\text{Si} & - \text{O}^+ \\
\end{align*}
\]

Alkylaryl ethers and diaryl ethers undergo protonation on either oxygen or carbon, depending upon the acidity of the medium (Scheme 4.3). Both the C-protonated species 28 and the O-protonated species 29 have been observed. The evidence mainly comes from NMR and UV data. Sommer et al. have used para-anisaldehyde as an indicator in acidity measurements in the superacidity range. The barrier of rotation around the Cipso–O bond upon O-protonation has been used as a criterion in such studies. The torsional barrier around the phenyl–alkoxy bond in the C-protonated forms of aromatic ethers has also been measured by spin-saturation transfer measurements.

4.2.1.4. Tertiary Oxonium Ions. The synthesis, structural characterization, and chemistry of compounds containing trivalent, positively charged oxygen (R3O+) have

\[
\begin{align*}
\text{R} & \quad \text{H} \\
\text{R} & \quad \text{H} \\
\text{R} & \quad \text{H} \\
\text{R} & \quad \text{H} \\
\text{R} & \quad \text{H} \\
\text{R} & \quad \text{H} \\
\text{R} & \quad \text{H} \\
\end{align*}
\]
been extensively investigated and reviewed\textsuperscript{1,90} since Meerwein pioneering work on tertiary oxonium ions in 1937.\textsuperscript{91}

Trialkyloxonium salts are generally prepared by the alkylation of dialkyl ethers.\textsuperscript{1,90} Alkyl halides can be used as alkylating agents in the presence of strong halide acceptors such as BF\textsubscript{3}, PF\textsubscript{5}, SbCl\textsubscript{3}, and SbF\textsubscript{5} [Eq. (4.13)].\textsuperscript{91}

\[
R_2O + SbCl_5 + R\text{Cl} \rightarrow R_3O^+ SbCl_6^- \quad (4.13)
\]

A metathetic silver salt reaction\textsuperscript{92} has been employed to prepare bicyclo[2.2.2]octyl-1-oxonium hexafluoroantimonate 30 [Eq. (4.14)].

\[
\text{R}_2O^+ + \text{AgSbF}_6 \rightarrow \text{R}_3O^+ \text{SbF}_6^- + \text{AgI} \quad (4.14)
\]

The analogous reaction, the alkylation of methyl (trimethylsilyl)methyl ether with alkyl iodide/AgBF\textsubscript{4}, and the reaction in Eq. (4.15) have been employed to prepare tertiary [(trimethylsilyl)methyl]oxonium salts.

\[
\text{Me}_3\text{SiCH}_2\text{Br} + \text{AgBF}_4 \xrightarrow{\text{CH}_2\text{Cl}_2, \text{RT}} \text{Me}_3\text{SiCH}_2O^+ \text{BF}_4^- + \text{AgBr} \quad (4.15)
\]

Trialkyloxonium salts can also be prepared by the reaction of secondary oxonium ion salts with diazoalkanes\textsuperscript{93} [Eq. (4.16)].

\[
\text{R}^+\text{H SbCl}_6^- + \text{RN}_2 \xrightarrow{\text{ClICH}_2\text{CH}_2\text{Cl}} \text{R}^-\text{R'}\text{SbCl}_6^- + \text{N}_2 \quad (4.16)
\]

Disproportionation of dialkyl ether–PF\textsubscript{5} adducts also give trialkyloxonium ions\textsuperscript{94} [Eq. (4.17)].

\[
3R_2O \xrightarrow{\text{RT}} PF_5 \rightarrow 2R_3O^+ PF_6^- + F_3P=O \quad (4.17)
\]

Another important synthesis method is transalkylation reactions with other oxonium ions.\textsuperscript{95} However, these reactions are reversible to a certain extent. The equilibrium between two oxonium salts and the corresponding ethers in solution is established by both differences in solubility and stability of the oxonium salts (Scheme 4.4). By an exchange reaction of this type, the trimethyloxonium salt 31 can be
prepared in excellent yield (86–94%) from the readily available triethyloxonium salt\(^95,96\) [Eq. (4.18)].

\[
2(CH_3CH_2)_3O^+BF_4^- + 3(CH_3)_2O \rightarrow 2(CH_3)_3O^+BF_4^- + 3(CH_3CH_2)O
\]

\[31\]

(4.18)

In many cases, the main step in the syntheses of trialkyloxonium salts is the alkylation of a dialkyl ether with a reactive intermediate oxonium ion formed in situ. Thus, the most widely used method for preparing trialkyloxonium tetrafluoroborates by the reaction of epichlorohydrin and BF\(_3\) is based on the intermediacy of the inner oxonium salt\(^32\)\(^91,95,97\) [Eq. (4.19)].

This method has been used by Minkwitz, Christe, and co-workers\(^98\) to synthesize perfluoroalkyl-substituted trialkyloxonium salts. X-ray crystal structure analysis of 33 (R\(_F\) = CF\(_3\)) shows that replacement of a methyl group in trimethylxonium cation by the bulkier and more electronegative CF\(_3\) group results in increases in both the Me-O bond lengths and the C-O-C bond angles (by 0.037 Å and 4.5°, respectively). Whereas pronounced deshielding of both the \(\alpha\)-methyl protons and \(\alpha\)-methyl carbons are observed in trialkyloxonium ions compared with the parent ethers, the shielding effect of the perfluoroalkyl substituent is small.

\end{align*}
\]

\[33\]
The method has been extended by the use of reactive intermediate oxonium ions such as sulfonyle cation–ether adducts, dialkylxoxybenzenium salts with ether, and so on. The more reactive dialkyl halonium ions also readily alkylate dialkyl ethers to the corresponding oxonium ions.\(^\text{99}\)

Olah and co-workers\(^\text{47,100}\) have recently reported experimental and theoretical studies of the trimethyloxonium ion \(\text{Me}_3\text{O}^+\). An early study\(^\text{29}\) resulting in inconclusive results has been repeated and the \(^{17}\text{O}\) NMR spectra of \(\text{Me}_3\text{O}^+\text{PF}_6^-\) salt was observed.\(^\text{100}\) A sharp peak at \(\delta^{17}\text{O} = 32.1\) was recorded, which is deshielded by 20.4 ppm compared to the experimental \(^{17}\text{O}\) NMR shift of the parent \(\text{Me}_2\text{O}\) \((\delta^{17}\text{O} = 52.5)\), which agrees well with the deshielding effect of 21 ppm calculated by the GIAO-MP2 method. Although not yet observed experimentally, the protonated trimethyloxonium dication \(\text{Me}_3\text{OH}^2+\) is a stable species both thermodynamically and kinetically \((\text{MP2/6-31G*/HF/6-31G* level})\).\(^\text{47,100}\) The tetramethyloxonium dication \(\text{Me}_4\text{O}^2+\) was found to be a stable minimum \((\text{HF/6-31G*})\).\(^\text{47}\)

In contrast to trialkyloxonium salts, the triphenyloxonium salt \(^\text{34}\) can be obtained by the reaction of benzenediazonium tetrafluoroborate with diphenyl ether in poor \((2\%)\) yield \([\text{Eq. (4.20)}]\) and is extremely inert toward nucleophiles. This fact is clearly demonstrated by the remarkable stability of triphenyloxonium halides \((\text{Cl}^-, \text{Br}^-, \text{I}^-)\).\(^\text{101-103}\)

\[
\begin{align*}
\text{Ph}_2\text{O} + \text{PhN}_2^+\text{BF}_4^- & \rightarrow \text{Ph}_3\text{O}^+\text{BF}_4^- \\
\text{4.20} & \text{34}
\end{align*}
\]

The surprising stability of triaryloxonium ions has been demonstrated by the fact that reduction of the tris(4-nitrophenyl)oxonium tetrafluoroborate \(^\text{35}\) can be performed to give the tris(4-aminophenyl)oxonium salt \(^\text{36}\) without cleavage of aryl oxygen bonds \([\text{Eq. (4.21)}]\). Diazotation of this amino derivative and reaction with iodide leads to the tris(\text{para}-iodophenyl)oxonium salt \(^\text{37}\) in excellent yields.\(^\text{104}\)

\[
\begin{align*}

\]

Dialkylaryl- or alkyldiaryl-oxonium ions are less stable and are prepared by alkylation of alkylaryl ethers or diaryl ethers with either methyl or ethyl hexafluoroantimonate in \(\text{SO}_2\text{ClF}\) at low temperatures.\(^\text{105,106}\) Dialkylaryloxonium ions are stable below \(-70^\circ\text{C}\); above this temperature they are transformed into ring-alkylated alkxybenzenes. These onium ions are stronger alkylating agents than trialkyloxonium ions, as shown by the immediate formation of trimethyloxonium ion from dimethylphenyloxonium ion and dimethyl ether (the reverse alkylation of anisole fails with trimethyloxonium salt).

The protons of methyl and methylene groups in the \(\alpha\)-position of the oxonium center of trialkyloxonium ions exhibit a deshielding effect of 1 ppm in the \(^1\text{H}\) NMR spectra compared with protons of the corresponding dialkyl ethers.\(^\text{107,108}\)
A deshielding effect of 15–20 ppm is also observed in the $^{13}$C NMR spectra. The spectra generally reflect the expected result of replacing a neutral center by a positively charged one.

The geometry of trialkyloxonium salts has been presumed to be pyramidal rather than planar. This assumption has been proved by an NMR experiment in which pyramidal oxygen inversion in the case of the $O$-alkylethyleneoxonium ion 38 was unambiguously demonstrated.

At $+40^\circ$C, the $^1$H NMR spectrum of 38 contains a very sharp singlet due to the ring protons. As the temperature is lowered, the ring proton resonance broadens to coalescence at $-50^\circ$C. At lower temperatures ($-70^\circ$C) the signal sharpens to a closely coupled ($v_{AB} \sim 3$ Hz) $AA'BB'$ spectrum. Thus, at the lowest temperature, the slowing of the rate of oxygen inversion results in the nonequivalence of the ring protons. The activation energy of the pyramidal inversion has been determined to be $10 \pm 2$ kcal mol$^{-1}$. The NMR spectra of six-membered cyclic oxonium ions are temperature-independent; therefore, even at $-70^\circ$C, rapid oxygen inversion must be assumed. Further evidence for the pyramidal nature of trialkyloxonium salts comes from X-ray crystallographic studies on triethyloxonium ion. On the contrary, the triphenyloxonium ion has a planar structure.

In a recent theoretical study [MP2, B3LYP, CCSD(T)] the inversion at the oxygen of the $O$-methylated oxirane cation 39 was calculated to be 15.7 kcal mol$^{-1}$, which agrees well with the experimentally determined value for cation 38. Cation 39 is kinetically stable because a high-energy barrier (35.3 kcal mol$^{-1}$) separates it from the ring-opened, significantly more stable isomeric oxonium ions (Scheme 4.5).
comparison, there are two major differences in the behavior of the \(O\)-methylated
tetramethyloxirane cation. (i) The potential energy surface is much shallower and, in
particular, the barrier to ring opening is much smaller. In fact, it is essentially identical
to that of the oxygen inversion \([\sim 15 \text{ kcal mol}^{-1} \text{ (MP2) or } \sim 11 \text{ kcal mol}^{-1} \text{ (B3LYP)}]\).
(ii) The hydride migration associated with ring opening of cation 39 is a concerted
process, as opposed to the stepwise methyl shift for the tetramethyl analog.

The unusual tertiary cage cation 40 (1-oxoniaadamantane) has recently been
synthesized and characterized by Olah, Prakash, and co-workers\(^\text{113a}\) using various
approaches [Eq. (4.22)]. The main characteristics of the \(^{13}\text{C}\) NMR spectrum are
triplets of the methylene groups (OCH\(_2\) at \(\delta^{13}\text{C} \approx 94.6\) and CH\(_2\) at \(\delta^{13}\text{C} \approx 31.7\)) and a
doublet of the bridgehead carbon at \(\delta^{13}\text{C} \approx 28.2\). X-ray analysis of single crystals of
the unsubstituted cation with the low nucleophilicity carborane anion CB\(_{11}\)H\(_6\)Cl\(_6^-\)
reveals no unusual bond features. A highly stable bridgehead oxoniatriquinane
cation has been prepared and characterized\(^\text{113b}\).

\[

\end{array}
\]

Trialkyloxonium ions have been extensively used to carry out \(O\)-alkylation
of lactams, amides, sulfoxides, oxo-sulfonium ylides, \(N\)-alkylation of \(N\)-heterocycles,
\(S\)-alkylation of thioethers, thioacetals, thioamides, and thiolactams.\(^\text{110}\) Although trialkyloxonium ions do not alkylate benzene or toluene directly, alkylation readily occur in
combination with highly ionizing superacids such as HSO\(_3\)F–SbF\(_5\). This may indicate
protosolvation of a nonbonded electron pair on oxygen in the superacid medium.

Silyloxonium ions, which are key intermediates in cationic polymerization of
cyclosiloxanes, have been prepared by treating diethyl ether according to
Scheme 4.6.\(^\text{114}\) A similar route has been applied to synthesize cyclic silyloxonium
ions 41. Trisilyloxonium ions 42 and 43 have been generated by reacting Me\(_3\)SiH with
Ph\(_3\)C\(^+\)(C\(_6\)F\(_5\))\(_4\)B\(^-\) in the presence of siloxanes.\(^\text{115,116}\)

\[

\end{array}
\]

The intermediacy of trimethyloxonium ion has been proposed in the first step of
the acid–base-catalyzed conversion of methyl alcohol into gasoline range hydrocarbons
over WO\(_3\)–Al\(_2\)O\(_3\).\(^\text{117}\) The crucial step is the base-catalyzed subsequent
deprotonation of the trimethyloxonium ion to the very reactive surface-bound
methylene-dimethyloxonium ylide. The ylide subsequently undergoes alkylation at its negative pole, and the resulting ethyldimethyloxonium ion then cleaves to give ethylene and dimethyl ether. The key to the success of such reactions is the use of bifunctional catalysts that have both acidic and basic sites.

4.2.1.5. Aurated Oxonium Ions. A variety of oxonium gold complexes with triaryl-, trialkyl-, alkylaryl-, and trialkoxyphosphine ligands (44) have been synthesized according to the general synthesis methods in Eq. (4.23). Since LAu⁺ is isolobal with H⁺—that is, they have similar bondings—complexes 44 represent the isolobal analog of H₃O⁺. Some of the complexes were characterized by X-ray crystallography and shown to have trigonal pyramidal structure in the solid state. The cations are associated with edge-to-edge contact (Au–Au distances about 3.10 Å) to form a square, but this may be disrupted with a sufficiently large phosphine ligand such as (ortho-tolyl)₃P. The smallest phosphine ligand (Me₃P), however, allows the formation of a new structural unit [(Me₃PAu)₆O₂]²⁺(BF₄⁻)₂, with aggregation through crossed edges to give a tetrahedron. Factors influencing aggregation behavior were addressed in subsequent theoretical calculations (LCGTO-DF approach).

\[
\begin{align*}
3\text{LAuCl} + \text{Ag}_2\text{O} &\rightarrow \text{(LAu)}_3\text{O}^+\text{BF}_4^- \quad \text{KOH} \rightarrow \text{LAu}^+\text{BF}_4^- \\
\text{L} &\equiv \text{Me}_3\text{P, Et}_3\text{P, tert-Bu}_3\text{P, cyclohexyl}_3\text{P, Ph}_3\text{P, (2-MeC}_6\text{H}_4\text{)}_3\text{P, Mes}_3\text{P, (4-CIC}_6\text{H}_4\text{)}_3\text{P, Ph}_2\text{Me}_3\text{P, Ph}_2\text{Et}_3\text{P, Ph}_2\text{isoPr}_3\text{P, PhMe}_2\text{P, Ph}_2\text{(OEt)}_3\text{P, (OME)}_3\text{P}.
\end{align*}
\]

Eq. (4.23)

Schmidbaur et al. have succeeded in synthesizing cations 45, which are gold analogs of the elusive double protonated water molecule H₄O²⁺ [Eq. (4.24)]. The central oxygen atom in the solid state is tetrahedrally coordinated to four gold atoms (characteristic data for the salt 45b: O–Au bond lengths = 2.0571 Å; Au–O–Au bond angles = 109.5°; Au–Au contacts = 3.3593 Å). The three ortho-tolyl groups at phosphorus form propellers of C₃ symmetry and are directionally disordered (right- or left-handed). The products are thermally very stable and show only one resonance in the ³¹P NMR spectrum at ambient temperature. At very low temperature (−90°C) the ³¹P NMR singlet of cation 45b but not 45a is split into a closely separated set of signals. This change arises from the relative orientation of the four (ortho-tolyl)₃P propellers,
which are not able to change the sign of rotation by concerted ortho-tolyl rotation on the NMR time scale. Since the hindrance of rotation of the phenyl groups in cation 45a is much less, no splitting is observed.

\[
\text{(Ar}_3\text{PAu)}_3\text{O}^+\text{BH}_4^- + \text{Ar}_3\text{PAu}^+\text{BF}_4^- \xrightarrow{\text{THF, CH}_2\text{C}_2\text{Cl}_2, -78^\circ\text{C}} \begin{array}{c}
\text{Ar}_3\text{PAu}^+\text{PF}_6^-
\end{array}
\]

45

\(\text{a}\) \(\text{Ar} = \text{Ph}\)

\(\text{b}\) \(\text{Ar} = \text{o-tolyl}\)

\(\text{4.2.1.6. Hydrogen Peroxonium Ion (H}_3\text{O}_2^+\text{) and Derivatives.}\) The use of hydrogen peroxide as a source of electrophilic oxygen under acidic conditions is gaining increasing importance. The hydrogen peroxonium ion \(\text{H}_3\text{O}_2^+\) has been invoked as an intermediate in the electrophilic hydroxylation of aromatics, oxygenation of alkanes, and so on. The hydrogen peroxonium ion \(\text{H}_3\text{O}_2^+\) has been isolated under superacid conditions. \(\text{H}_2\text{O}_2\) is also protonated in HF–MF\(_5\) (\(\text{M} = \text{Sb, As}\)) solutions [Eq. (4.25)].

\[
\text{H}_2\text{O}_2 + \text{HF} + \text{MF}_5 \xrightarrow{} \text{H}_3\text{O}_2^+\text{MF}_6^- \quad (4.25)
\]

The \(\text{H}_3\text{O}_2^+\text{MF}_6^-\) salts are white crystalline solids with marginal stability. They exothermically decompose at room temperature to hydronium ion salt and molecular oxygen [Eq. (4.26)].

\[
\text{H}_3\text{O}_2^+\text{MF}_6^- \xrightarrow{} \text{H}_3\text{O}^+\text{MF}_6^- + 0.5 \text{O}_2 \quad (4.26)
\]

A detailed infrared analysis shows that the ion possesses \(C_s\) symmetry similar to its isoelectronic analog \(\text{NH}_2\text{OH}\). The \(\text{H}^1\) NMR spectrum of 46 in HF–AsF\(_5\) solution at \(-80^\circ\text{C}\) shows only one broad signal at \(\delta^1\text{H} 11.06\) indicating rapid proton exchange between 46 and the HF solution. This was subsequently confirmed by \(\text{O}^{17}\)NMR spectroscopy. The \(\text{H}_3\text{O}_2^+\) ion 46 has a \(\text{O}^{17}\)NMR chemical shift of \(\delta^{17}\text{O} 151\) (with respect to \(\text{SO}_2\) at 505 ppm) and shielded by 36 ppm with respect to hydrogen peroxide.

The crystal structure of \(\text{H}_3\text{O}_2^+\text{SbF}_6^-\) has been determined by Minkwitz et al.\(^{128}\) An interesting feature of the cation 46 is that the O–O bond distance (1.443 Å) is slightly shorter than the bond length in free hydrogen peroxide (1.461 Å by X-ray diffraction and 1.458 Å by neutron diffraction\(^{129}\)). This indicates that the conversion of the lone pair of electrons into a bonding electron pair strengthens the weak O–O bond in hydrogen peroxide.
The synthetic utility of hydrogen peroxonium ion reagent is discussed in Chapter 5. Similarly, protonation and cleavage reactions of hydroperoxides and peroxides have been investigated extensively\textsuperscript{125} and are also discussed in Chapter 5.

Mitchell and co-workers\textsuperscript{130–132} have studied substituted derivatives of hydrogen peroxide intermediates in organic transformations. Ions 47 and 48 were prepared from the corresponding bromoperoxides with AgBF\textsubscript{4} and trapped in appropriate reactions. When ionization was performed in SbCl\textsubscript{5}, the NMR spectra of the reaction mixture (downfield singlets at δ\textsuperscript{1}H 6.29 and 6.14 assigned to the methylene protons) gave compelling evidence of the existence of cation 48.\textsuperscript{131} Further support comes from a similar study of the tetradeutero derivative.

\[
\begin{align*}
\text{47} & \quad \text{O}^+ \text{tertBu} \\
\text{48} & \quad \text{O}^+ \text{tertBu}
\end{align*}
\]

Minkwitz and Gerhard\textsuperscript{133} have isolated protonated dimethyl peroxide MeOO(H)Me\textsuperscript{+} prepared by protonating dimethyl peroxide in HF–AsF\textsubscript{5} and reported characterization by \textsuperscript{1}H NMR and vibrational spectroscopy. Their efforts to obtain the trimethylperoxonium ion, however, were unsuccessful. Subsequently, however, Olah, Prakash, Christe, and co-workers\textsuperscript{134} reported the preparation and NMR spectroscopic characterization of the MeOOMe\textsubscript{2}\textsuperscript{+} ion 49 as a long-lived species [Eq. (4.27)]. The \textsuperscript{1}H NMR spectrum showed two singlets [δ\textsuperscript{1}H 5.26 (6H) and 4.95 (3H)]. The \textsuperscript{13}C NMR chemical shift at δ\textsuperscript{13}C 85.6 (s) assigned to the methyl groups attached to the oxonium center is deshielded by 24.2 ppm compared to that of the methyl group in MeOOMe. The carbon chemical shift at δ\textsuperscript{13}C 70.8 (s) assigned to the methyl group on the uncharged oxygen, in turn, is only 9.4 ppm deshielded. This indicates that the positive charge is mostly localized on the tricoordinate oxygen atom.

\[
\text{MeOOMe + MeF} \xrightarrow{\text{SbF}_5–\text{SO}_2} \text{MeO}^+ \text{SbF}_6^- \quad \text{Me} \quad \text{Me} \quad \text{O}^+ \quad \text{Me} \quad \text{Me}
\]

\[ (4.27) \]

\textbf{4.2.1.7. Ozonium Ion (HO\textsubscript{3}\textsuperscript{+}).} Ozone is a resonance hybrid of canonical structures 50a–50d\textsuperscript{135} Ozone does in fact act as a 1,3-dipole—that is, either as an electrophile or a nucleophile. The electrophilic nature of ozone has been recognized for a long time in its reactions with alkenes, alkynes, arenes, amines, phosphines,
sulfides, and so on. However, its reactivity as a nucleophile has not been well-recognized.

Ozone has been shown to be protonated in the superacid media to ozonium ion $\text{HO}_3^+$ [Eq. (4.28)], which reacts with alkanes as a powerful electrophilic oxygenating agent. Similarly, ozone reacts with carbocations, giving alkylated ozonium ion that undergoes further cleavage reactions. These reactions are well-covered in Chapter 5.

$$\text{HO}_3^+ + \text{H}^+ \rightarrow \text{HO}^- - \text{O}^+$$  

The long elusive ozonium ion $\text{HO}_3^+$ has been experimentally detected in the gas phase with the use of Fourier transform ion cyclotron resonance (FT–ICR) generated by reacting ozone with strong Brønsted acids ($\text{H}_3^+$, $\text{KrH}^+$, $\text{XeH}^+$, $\text{CH}_5^+$). The proton affinity of ion $\text{HO}_3^+$ determined with the bracketing technique is $148 \pm 3 \text{ kcal mol}^{-1}$ at 298 K. This value is in excellent agreement with those calculated at various levels of theory (CCSDT-1 level $= 146.8$–$149.5 \text{ kcal mol}^{-1}$; BP, BPRO, PP91, PW98 levels $= 146.8$–$149.5 \text{ kcal mol}^{-1}$). Varied values have recently been computed at more advanced levels including temperature and entropy effects. The absolute minimum on the potential energy surface is a structure with terminally attached proton in trans arrangement to the O(2)–O(3) bond. The cis isomer is $3.6 \text{ kcal mol}^{-1}$ higher in energy.

4.2.2. Sulfunium Ions

4.2.2.1. Hydrosulfunium Ion ($\text{H}_3\text{S}^+$). The parent of sulfunium ions is the protonated $\text{H}_2\text{S}$, the hydrosulfunium ion $\text{H}_3\text{S}^+$ 52. Olah et al. observed ion 52 for the first time in $\text{HSO}_3\text{F–SbF}_5–\text{SO}_2$ media at low temperature by $^1\text{H}$ NMR spectroscopy. $\text{H}_3\text{S}^+$ appeared as a singlet at $\delta^1\text{H} 6.6$ from tetramethylsilane. Christe has isolated $\text{H}_3\text{S}^+\text{SbF}_6^-$ salt by treating $\text{H}_2\text{S}$ with HF–$\text{SbF}_5$ [Eq. (4.29)].

$$\text{H}_2\text{S} + \text{HF} + \text{SbF}_5 \rightarrow \text{H}_3\text{S}^+\text{SbF}_6^-$$  

The hexafluoroantimonate salt of 52 is a stable white solid that reacts with water to produce $\text{H}_2\text{S}$. This reaction can be conveniently used to generate $\text{H}_2\text{S}$. The ion 52 has been thoroughly characterized by vibrational spectroscopy and normal coordinate analysis.
Cation 52 has also been studied in the gas phase by mass spectrometry. In addition, SH$_3^+$ and its isotopomers (H$_3$S$^+$, HD$_2$S$^+$, D$_3$S$^+$) were also observed by various spectroscopic methods. The structure and energy of ion 52 have been calculated by ab initio method [MP2/6-311(2df,2pd) level]. Ion 52 is of C$_3$v symmetry and has a bond angle of 94.2°, which is slightly larger than that of H$_2$S (92.1°). This is attributed to the positive charge resulting in the contraction of the lone electron pair of sulfur, thus leaving more room for the bonding electrons of the S–H bonds.

Olah et al. have observed that the sulfonium ion H$_3$S$^+$ undergoes hydrogen–deuterium exchange in superacid media, indicating the involvement of diprotonated hydrogen sulfide (tetrahydridosulfonium ion) H$_4$S$^{2+}$. The structure of T$_d$ symmetry was found to be the minimum energy structure at the HF/6-31G* level. Dication H$_4$S$^{2+}$ is thermodynamically unstable (dissociation energy = 25.2 kcal mol$^{-1}$), but has a significant kinetic barrier (59.2 kcal mol$^{-1}$) for deprotonation. The values calculated by Boldyrev and Simons are $-91.4$ kcal mol$^{-1}$ and 19.7 kcal mol$^{-1}$, respectively (QCISD(T)/6-311G(2df,2p)/MP2(full)/6-31G** level). Olah, Rasul, and Prakash have calculated the structure of the trication H$_5$S$_3^+$ (MP2/6-31G** and QCISD(T)/6-311G** levels). The minimum-energy structure of C$_5$ symmetry resembles a complex between H$_3$S$^{3+}$ and a hydrogen molecule forming a two-electron three-center bond. The S–H bond lengths in the 2e–3c system (1.622 and 1.624 Å) are about 0.2 Å longer than normal S–H bonds. Similarly, the H–H bond distance in the 2e–3c bond (1.028 Å) is longer by about 0.29 Å than that in the H$_2$ molecule.

4.2.2.2. Primary Sulfonium Ions. Aliphatic thiols are completely protonated in HSO$_3$F–SbF$_5$ diluted with SO$_2$ at $-60^\circ$C [Eq. (4.30)].

$$\text{RSH} + \text{HSO}_3\text{F}^- + \text{SbF}_5^- + \text{SO}_2 \rightarrow \text{RSH}^+ + \text{SbF}_5^- + \text{SO}_2^- \quad (4.30)$$

The proton at sulfur is at considerably higher field in the $^1$H NMR ($\delta^1$H 5.93–6.45) than the corresponding proton on oxygen in protonated alcohols ($\delta^1$H 9.1–9.5), reflecting the larger size of the sulfur atom compared with oxygen. The protonated thiols are considerably more stable than protonated alcohols. Protonated tert-butyl thiol 53 shows no appreciable decomposition at $-60^\circ$C in HSO$_3$F–SbF$_5$–SO$_2$, whereas protonated tertiary alcohols could not be observed under similar conditions and even protonated secondary alcohols cleave at a significant rate. Protonated thiols cleave at higher temperature to give protonated hydrogen sulfide (singlet, $\delta^1$H 6.60) and stable alkyl cations. For example, protonated 2-methylpropane-2-thiol 53 slowly cleaves to tert-butyl cation and protonated hydrogen sulfide when the temperature is increased to $-30^\circ$C ($t_{1/2} \sim 15$ min) [Eq. (4.31)]. Protonated 2-methylbutane-2-thiol 54 also cleaves at this temperature to the tert-amyl cation [Eq. (4.32)].

$$\text{(CH}_3\text{)}_2\text{CSH}_2^+ \xrightarrow{\text{H}^+ \text{, } -30^\circ\text{C}} \text{(CH}_3\text{)}_2\text{C}^+ + \text{H}_3\text{S}^+ \quad (4.31)$$
Protonated secondary thiols are stable even at higher temperatures. Protonated isopropyl thiol cleaves slowly at 0°C in HSO₃F–SbF₅ (1:1 M) solution. No well-identified carbocations were found in the NMR spectra due to the instability of the isopropyl cation under these conditions. Protonated sec-butyl thiol cleaves to tert-butyl cation at this temperature [Eq. (4.33)].

$$\text{CH}_3\text{CH}_2\text{CH}_2\text{SH}_2^+ + \text{H}^+ \rightarrow [\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_3]^+ - \text{H}_3\text{S}^+$$

Protonated primary thiols are stable at much higher temperatures. Protonated n-butyl thiol cleaves to tert-butyl cation only at +25°C [Eq. (4.34)].

$$\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{SH}_2^+ + \text{H}^+ \rightarrow [\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2]^+ - \text{H}_3\text{S}^+$$

Minkwitz et al. have prepared monoalkylsulfonium salts by protonation of the corresponding thiols in superacids [Eq. (4.35)]. Monofluorosulfonium hexafluorantimonate, in turn, was generated by oxidative fluorination of H₂S with equimolar amount of XeF⁺SbF₆⁻ [Eq. (4.36)]. Excess of either reagent results in decomposition into S₈²⁺(SbF₆⁻)₂. Crystal structure analysis of the isoPrSH₂⁺SbF₆⁻ salt gave the first experimentally determined S–H bond distance (1.12 Å).

$$\text{H}_2\text{S} + \text{XeF}^+\text{SbF}_6^- \rightarrow \text{F}^-\text{S}^+\text{SbF}_6^- + \text{Xe}$$

Mercaptosulfonium salts H₃S₂⁺MF₆⁻ (M = As, Sb), analogs of protonated hydrogen peroxide, have been prepared [Eq. (4.37)] and characterized by vibrational spectroscopy by Minkwitz et al. According to calculations (ab initio, general force field), the cation has a conformation with the lone pair of H₂S⁺ antiperiplanar to the S–H bond.
4.2.2.3. Secondary Sulfonium Ions. Protonated aliphatic sulfides have been studied at low temperatures by NMR spectroscopy in strong acid systems\textsuperscript{149} [Eq. (4.38)]. They show well-resolved NMR spectra, with the proton on sulfur being observed at about $\delta^1H \approx 6.0$.

\begin{equation}
\text{RSR} \quad \xrightarrow[\text{HSO}_3\text{F–SbF}_5\text{SO}_2]{\text{−60°C}} \quad \text{S}^+\text{H SbF}_5\text{FSO}_3^- \quad (4.38)
\end{equation}

The NMR spectrum of protonated thiane-3,3,5,5-$d_4$ has also been studied in HSO$_3$F–SbF$_5$ to determine the conformational position of the proton on sulfur in the six-membered ring and to study the ring inversion process.\textsuperscript{162} The proton on sulfur resides exclusively in the axial position.

The protonated sulfides are less susceptible to cleavage than the corresponding protonated ethers and also more stable than the protonated thiols.\textsuperscript{149} Protonated tert-butyl methyl ether is completely cleaved to tert-butyl cation and protonated methanol even at $−70^\circ\text{C}$. On the other hand, protonated tert-butyl methyl sulfide $60$ is stable even at $−60^\circ\text{C}$. When the temperature is increased to $−15^\circ\text{C}$, protonated tert-butyl methyl sulfide very slowly cleaves to tert-butyl cation and protonated methyl thiol\textsuperscript{149} [Eq. (4.39)].

\begin{equation}
\text{(CH}_3\text{)}_3\text{C}^+ \quad \xrightarrow[\text{H}^+]{\text{−15°C}} \quad \text{(CH}_3\text{)}_3\text{C}^+ \quad + \quad \text{CH}_3\text{SH}_2^+ \quad (4.39)
\end{equation}

Protonated di-tert-butyl sulfide $61$ shows very little cleavage at $−60^\circ\text{C}$. At $−35^\circ\text{C}$ it cleaves slowly ($t_{1/2} \sim 1\text{ h}$) to tert-butyl cation and protonated hydrogen sulfide [Eq. (4.40)], with the latter showing the $^1H$ NMR peak at $\delta^1H \approx 6.60$.

\begin{equation}
\text{(CH}_3\text{)}_3\text{C}^+ \quad \xrightarrow[\text{H}^+]{\text{−35°C}} \quad \text{(CH}_3\text{)}_3\text{C}^+ \quad + \quad \text{(CH}_3\text{)}_3\text{C}SH_2^+ \quad \xrightarrow[\text{H}^+]{\text{−15°C}} \quad \text{(CH}_3\text{)}_3\text{C}^+ \quad + \quad \text{H}_2\text{S}^+ \quad (4.40)
\end{equation}
Protonated secondary sulfides show extraordinary stability toward the strongly acidic medium. Protonated isopropyl sulfide shows no appreciable cleavage up to +70°C in a solution of HSO₃F–SbF₅ (1:1).

Protonation of dimethyl sulfide and di-tert-butyl sulfide with HF–MF₅ (M = As, Sb) has been used to prepare the corresponding secondary dialkylsulfonium salts.¹⁶³ Oxidative fluorination with XeF⁺SbF₆⁻ has also been used to generate alkyl fluorosulfonium hexafluorometalates¹⁶⁴ [Eq. (4.41)]. The salts are thermally labile (decomposition is observed above −40°C) and exhibit ¹⁹F NMR chemical shifts at δ¹⁹F −177.0 (R = CH₃) and −133.2 (R = CF₃), which are downfield from those of the corresponding dialkyl-substituted derivatives [(CH₃)₂SF⁺ δ¹⁹F −190.7¹⁶⁵ and (CF₃)₂SF⁺ δ¹⁹F −159.4¹⁶⁶].

\[
\text{XeF}^+\text{MF}_6^- + \text{RSH} \xrightarrow{\text{HF, -60°C}} \text{R}^+\text{S}^+\text{MF}_6^- \quad (4.41)
\]

The protonation of cyclic sulfides have also been studied by Olah and Szilagyi.⁷⁹ Both protonated thiirane and methylthiirane could be observed by ¹H NMR spectroscopy (HSO₃F–SbF₅–SO₂ solution, −78°C). Protonated thiirane gives a complex symmetrical spectrum (A₂B₂X) centered at δ¹H 3.63 deshielded by 1.30 ppm from the precursor but the SH proton could not be observed. Protonation of thiirane-1-oxide studied for comparison, occurred at the sulfur atom and the ion exhibited ring protons at δ¹H 3.87 deshielded from δ¹H 2.47 of the precursor. The SH proton was observed at δ¹H 5.27. Protonation of the larger homologs were also successful. The SH proton resonances appear at consistently higher field (average 6.30 ppm) than those of the corresponding acyclic sulfides (average 7.61 ppm). Furthermore, ¹H NMR chemical shifts of thiiranes are more shielded than those of oxiranes, and both are more shielded when compared with those found for cyclic iodonium and bromonium ions. The same tendency was observed for the corresponding five-membered cyclic protonated derivatives.

4.2.2.4. Tertiary Alkyl(Aryl)Sulfonium Ions. In contrast to tertiary oxonium ions, the tertiary sulfonium ions are stable and are prepared rather readily.¹⁶⁷–¹⁶⁹ They are even stable in aqueous solutions. Trialkylsulfonium ions are obtained by alkylation of dialkyl sulfides with alkyl halides. Trialkyloxonium and dialkyhalonium ions readily transalkylate basic dialkylsulfides.

In contrast, alkylation of diaryl sulfides and thiophene requires rather drastic conditions due to poor nucleophilicity of sulfur. The alkylations have been achieved using alkyl triflates¹⁷⁰ [Eq. (4.42)] or with alkyl halide and silver tetrafluoroborate¹⁷¹ [Eq. (4.43)].
Another method is the use of esters as alkylating agents in triflic acid\cite{172} [Eq. (4.44)]. This method has been used to synthesize $S$-methylated phenylene sulfide oligomers (methyl triflate, triflic acid, 25°C, 10 h) and to solubilize poly(phenylenesulfide) by transforming it to poly(arylenesulfonium) salts \textit{62} (methyl triflate, methyl or ethyl formate, triflic acid, 110°C, 10 h). In a similar way, alkylation of thianthrene to yield the corresponding sulfonium salts (\textit{63}) has been achieved using alkyl formates.\cite{173}

\begin{equation}
R_S + R^1\text{COOR}^2 \xrightleftharpoons{\text{CF}_3\text{SO}_2\text{H}}^{20^\circ\text{C}, \, 10\, \text{h}} R^+_S - R^2\text{TfO}^-
\end{equation}

Cyclizations shown in Eq. (4.45) have been used to obtain $S$-perfluoroalkylbenzothiophenium ion \textit{64} and ring-substituted derivatives.\cite{174,175} Salts \textit{64} and the $S$-(difluoromethyl)- and $S$-(monofluoromethyl)-diarylthiophenium salts \textit{65} reported recently by Prakash, Olah, and co-workers\cite{176,177} are used as fluoromethylating agents.

\begin{equation}
\text{R}_F = \text{CF}_3, \, \text{C}_3\text{F}_7, \, \text{C}_8\text{F}_{17}
\end{equation}

The absolute configuration of ethylmethylpropylsulfonium ion, the simplest chiral sulfonium ion has been determined.\cite{178}
The most important application of trisubstituted sulfonium ions is in the generation of sulfur ylides.\textsuperscript{179}

Thiiranium ions (episulfonium ions) were first synthesized by Lucchini and co-workers\textsuperscript{180} and subsequently characterized by X-ray crystallography by Simonetta and co-workers.\textsuperscript{181} A number of thiiranium ions with bulky substituents capable of hindering the attack of nucleophiles have been isolated and characterized. The molecular structure of ion 66 shows two longer S–C bonds in the thiiranium ring with some asymmetry\textsuperscript{182} (1.970 and 1.987 Å). Ion 67 is dimeric in the solid state with shorter bonds and one ion exhibiting significant asymmetry\textsuperscript{183} (1.914 and 1.937 Å, 1.909 and 1.913 Å). The S–C ipso bonds are significantly shorter (66 = 1.784 Å, 67 = 1.789 Å). One of the adamantyl rings is twisted away from the plane of the thiiranium ring.

Lucchini, Pasquato, and co-workers have obtained stereoisomeric 2,3-disubstituted 1-methylthiiranium ions, reported characterization (\textsuperscript{1}H and \textsuperscript{13}C NMR, X-ray crystallography), and studied their anionotropic rearrangements. The synthesis was performed by reacting methylbis(methylthio)sulfonium salts with alkenes\textsuperscript{184,185} (Scheme 4.7).

Because of the steric interactions of the two tert-butyl groups,\textsuperscript{186} ion \textit{trans,trans}-68 features a longer C–C bond in the ring (1.500 versus 1.452 Å) and increased bond angles [C(3)–C(2)–C(4) = 135.4 versus 127.0°, C(2)–C(3)–C(5) = 135.4 versus 125.5°] as compared to ion \textit{cis,trans}-68. The interaction of S–Me with the nearest Me group of the tert-butyl group in ion \textit{cis,trans}-68 brings about an enlarged S–C(2)–C(4) angle with respect to S–C(3)–C(5) (125.1 versus 117.1°) and asymmetric S–C bonds (1.876 and 1.860 Å).

\begin{scheme}
(Scheme 4.7)
\end{scheme}
Ion \textit{cis, trans-68} undergoes rearrangement at room temperature in CD\(_2\)Cl\(_2\) to yield quantitatively the ring-enlarged product thiethanium ion \textit{69}. X-ray crystal structure characterization shows\(^{187}\) that the exocyclic S–C bond (1.797 Å) is significantly shorter than the endocyclic S–C bonds (1.864 and 1.896 Å). The difference (about 0.03 Å) between the latter two bonds is related to the steric hindrance between the two \textit{cis} Me groups. The lengthening of the ring S–C bonds and the torsion angle [C(1)–S–C(2)–C(3) = 12.2°] allows the separation of the two Me groups by 3.100 Å. This value, however, is still smaller than the sum of the van der Waals radii of the C atoms (3.4 Å). The four-membered ring has a puckering angle of 145.1°.

Thiirenium ion \textit{70}, synthesized as described in Scheme 4.7 in a reaction with the corresponding acetylene, exhibits an analogous behavior to yield the thiethium ion \textit{71}.\(^{188}\) Phenyl-substituted thiiranium ion \textit{72a} was shown to undergo rapid isomerization presumably through benzyl cations at −50°C to yield the \textit{trans} compound.\(^{189}\) In contrast, \textit{72b} is configurationally stable at 0°C. Stereoisomeric ions \textit{73a} and \textit{73b} prepared by methylation of the corresponding thiiranes (Scheme 4.8) undergo isomerization at room temperature and above.\(^{190}\)

Sulfonium ions are possible important reactive intermediates in stereoselective glycosylations, although their role has recently been disputed.\(^{191}\) A number of ions including \textit{74},\(^{192}75,^{193}\) and \textit{76}\(^{194}\) have been observed by low-temperature NMR spectroscopy, whereas the structure of \textit{77} was determined by X-ray crystallography.\(^{195}\)

The tertiary cage sulfonium cation \textit{78} was generated and characterized by NMR spectroscopy as early as 1963\(^{196}\) [Eq. (4.46)].
Sulfonium dication 79 with unusual bonds and charges has been prepared by Furukawa, Sato, and co-workers\textsuperscript{197,198} [Eq. (4.47)]. Both salts were characterized by NMR spectroscopy and X-ray crystallography. The data indicate that the dications have distorted tetrahedral configuration (bond angles of the tetrafluororborate salt are 94.9°, 115.9°, 117.5°, and 118.3°).\textsuperscript{197} Bond lengths are within those of normal tetrahedral sulfur compounds.
4.2.2.5. Halosulfonium Ions

Trihalosulfonium Ions. Of the parent trihalosulfonium ions, $X_3S^+$ ($X = F, Cl, Br$), $F_3S^+$ and $Cl_3S^+$ were reported first. The reaction product of $SF_4$ and $BF_3$ was described by Bartlett as the $SF_4/BF_3$ adduct, but it was subsequently proved by structural studies (NMR, Raman, IR) to be the $F_3S^+BF_4^-$ salt. According to crystal structure analysis, the ion $F_3S^+$ is of $C_3v$ symmetry and has very short $S/F$ bonds (1.495 and 1.499 Å) indicative of a substantial positive charge on sulfur. Other $F_3S^+MF_6^-$ ($M = As, P, Sb$) salts were studied by Gillespie and co-workers.

Various $Cl_3S^+MnF_6^-$ salts were prepared by Kolditz and Schäfer ($M_n = AsF_6$, oxidative chlorination of sulfur with $AsCl_3–AsF_3$), Minkwitz and Gerhard [Eq. (4.48)], and Passmore et al. [Eq. (4.49)]. The cation $Cl_3S^+$ in $Cl_3S^+AsF_6^-$ was found to be pyramidal ($C_3v$ symmetry) by X-ray structure analysis. The cations in $Br_3S^+SbF_6^-$ and $Cl_3S^+SbCl_6^-$, in turn, were shown to have significantly shortened sulfur–halogen bonds and distorted octahedral arrangement around sulfur, when cation–anion secondary bonding interactions are taken into account.

Dihalo-monoalkyl(aryl)sulfonium Ions. A general synthetic route to produce dihalo-monoalkyl(aryl)sulfonium salts is oxidative halogenations of $RSX$ with $AsCl_3–AsF_3$, $Mn$ [Eq. (4.50)]. Other approaches may also be used for the synthesis of $CF_3SCl_2^+AsF_6^-$ salts [Eq. (4.51)]. Ionization of $CF_3SF_3$ with Lewis superacids yields the corresponding $CF_3SF_2^+$ salts. The crystal structure of $CF_3SF_2^+AsF_6^-$ and $CF_3Cl_2^+SbF_6^-$ have been reported.

\[
\begin{align*}
H_3S^+SbF_6^- + 2Cl_2 & \rightarrow \text{Cl}_3S^+SbF_6^- + 3HCl \quad (4.48) \\
0.25S_8 + 3Br_2 + 3MF_5 & \rightarrow 2Br_3S^+MF_6^- + MF_3 \quad (4.49) \\
M &= As, Sb
\end{align*}
\]
C₆F₅SF₃ with Lewis superacids.¹⁶⁹ Significant deshielding of fluorines in *ortho* and *para* positions indicates charge dispersion into the aromatic ring. C₆F₅ derivatives were found to be more stable than their CF₃ counterparts.

Mixed chlorofluorosulfonium salts are prepared by oxidative halogenation of acid secondary sulfonium salts¹⁶⁴,²¹⁹ [Eq. (4.52)] or oxidative fluorination⁷₃,²¹⁷ with XeF²⁺ [Eq. (4.53)]. The products were characterized by spectroscopic methods (NMR, IR, Raman). CF₃S(Cl)F⁺SbF₆⁻ undergoes symmetrization in SO₂ solution to yield CF₃SF₂⁺SbF₆⁻ and CF₃SCl₂⁺SbF₆⁻.²¹⁷ The X-ray structure of the latter compound was also reported.

\[
\text{RS(H)F}^+\text{MF}_6^- + X_2 \xrightarrow{\text{HF}} \text{RS(X)}^+\text{MF}_6^- + \text{HX} \quad (4.52)
\]

\[
\text{CF}_3SX + \text{XeF}^+\text{MF}_6^- \xrightarrow{\text{HF/}\text{Xe}} \text{CF}_3S(X)^+\text{MF}_6^- \quad (4.53)
\]

**Dialkyl(diaryl)monohalosulfonium Ions.** These ions can readily be prepared by reacting dialkylsulfides with appropriate halogenating agents¹⁶⁹ [Eq. (4.54)]. Meerwein used this method to synthesize Me₂SCl⁺BF₄⁻ by anion exchange and also reacted Me₂S–SbCl₅ to obtain the corresponding hexachloroantimonate.²²⁰ Chlorination of Et₂S and isoPr₂S was also accomplished with excess SbCl₅.²²¹

\[
\text{R}_2\text{S} + \text{Cl}_2, \text{or NCIS, or SO}_2\text{Cl}_2 \xrightarrow{\text{HBF}_4} \text{R}_2\text{ClIs} + \text{Cl}^- \xrightarrow{\text{HBF}_4} \text{R}_2\text{ClIs} + \text{BF}_4^- \quad (4.54)
\]

Dialkylsulfoxides can also be transformed to R₂XS⁺ (X = Cl, Br) ions [Eq. (4.55)].

\[
\text{R}_2\text{SO} + \text{SOCl}_2 \xrightarrow{\text{HBF}_4 \text{or SbF}_5} \text{R}_2\text{ClIs} + Y^- \quad (4.55)
\]

In addition to the procedure developed by Meerwein [see Eq. (4.54)], Me₂XS⁺ salts have also been obtained according to the method shown in Eq. (4.56)²²² and by using XeF₂ as a reagent [Eqs. (4.57) and (4.58)].¹⁶⁵ Minkwitz and co-workers reported the synthesis of (CF₃)₂FS⁺ salts¹⁶⁶ [Eq. (4.59)] and the crystal structure of Me₂ClIs⁺SbF₆⁻ and Et₂ClIs⁺SbCl₆⁻.²²¹,²²²

\[
\text{Me}_2\text{SH}^+\text{SbF}_6^- + \text{Cl}_2 \xrightarrow{\text{SO}_2} \text{Me}_2\text{ClIs}^+\text{SbF}_6^- + \text{HCl} \quad (4.56)
\]

HF–SO2–40°C (CFS)2S+MF6− → HF–40°C (CF3)2S + XeF+MF6−

M = As, Sb

A comparison of 19F NMR chemical shifts of (CF3)2FS+, CF3F2S+, and F3S+ shows an increasing shielding with replacement of CF3 by F (δ19F = −159.0, −54.7, and 30.5, respectively).223 All three ions react with acetonitrile to form ψ-pentacoordinated ions [Eq. (4.60)]. NSF3 forms similar but weaker donor−acceptor complexes.

\[[\text{(CF3)}_n\text{SF3−n}]^+\text{AsF6}− + \text{CH3CN} \rightleftharpoons [\text{(CF3)}_n\text{SC3−n} \cdot \text{NCCH3}]^+\text{AsF6}−\] (4.60)

n = 0−2

Fluorination of (C6F5)2S with XeF+ has been applied to obtain (C6F5)2FS+MF6− (M = As, Sb) salts.224 An S–F bond distance of 1.584 Å was found by crystal structure analysis of (C6F5)2FS+SbF6−. Minkwitz et al.225,226 have reported the synthesis and structural characterization of the cyclic monofluorinated cations 81 and 82. The S–F bond lengths (1.51 and 1.522 Å) are significantly shorter than that in (C6F5)2FS+ (1.584 Å).

\] 82

4.2.2.6. Sulfonium Ions with Other Heteroligands

Hydroxy- and Alkoxysulfonium Ions. In addition to the well-documented formation of the SO2−–SbF5 complex in a mixture of the two components,227 Minkwitz and co-workers228 have recently detected the formation of the fluorodihydroxysulfonium cation 83 [Eq. (4.61)]. Crystal structure analysis of the isolated salt showed bond distances typical of S–O single bonds (1.537 and 1.522 Å) and S–F single bonds (1.547 Å). The steric demand of the lone electron pair of sulfur results in the compression of bond angles from the ideal tetrahedral arrangement
(F–S–O = 99.0 and 100.1°, O–S–O = 98.6°). A Raman line at 830 cm\(^{-1}\) may be assigned to the ion \(83\).

\[
2\text{HF} + \text{SbF}_5 \xrightarrow{-90^\circ\text{C}} \text{H}_2\text{F}^+\text{SbF}_6^- \quad \xrightarrow{-25^\circ\text{C}} \quad \text{SO}_2\text{SbF}_5 + 2\text{HF} \quad \text{(HO)}_2\text{FS}^+\text{SbF}_6^- \quad 83
\]

(4.61)

The existence of the trihydroxysulfonium ion \(\text{H}_3\text{SO}_4^+\) formed by autoprotolysis of sulfuric acid was confirmed by various experimental techniques. Minkwitz and colleagues\(^{229}\) have been able to prepare the ion using the technique, which was successfully applied in the generation of protonated hydrogen peroxide and carbonic acid [Eq. (4.62)]. The molecular structure of the colorless crystals of \(\text{D}_3\text{SO}_4^+\text{SbF}_6^-\) shows three \(\text{S}–\text{O}\) bonds with approximately the same bond lengths (1.499–1.512 \(\text{Å}\)). This bond length is intermediate between the \(\text{S}–\text{O}\) single and \(\text{S}=\text{O}\) double bond of sulfuric acid indicative of dispersion of the positive charge. The \(\text{S}=\text{O}\) double bond length is close to that in sulfuric acid (1.413 \(\text{Å}\) versus 1.426 \(\text{Å}\)). The cations and anions are linked by three hydrogen bondings.

\[
(\text{Me}_3\text{SiO})_2\text{SO}_2 + \text{XF} + \text{SbF}_5 \xrightarrow{-196 \text{ to } -78^\circ\text{C}} \text{X}_3\text{SO}_4^+\text{SbF}_6^- + 2\text{Me}_3\text{SiF}
\]

\(X = \text{H}, \text{D}\)

(4.62)

Olah and co-workers studied protonated dimethyl sulfoxide in \(\text{SbF}_5–\text{SO}_2\text{ClF}\) (or \(\text{SO}_2\)) solution and identified the \(\text{O}\)-monoprotonated \(\text{Me}_2\text{SOH}^+\) species by \(^1\text{H}\) and \(^{13}\text{C}\) NMR spectroscopy\(^{230}\) also indicated by a Raman study.\(^{231}\) The \(^{13}\text{C}\), \(^{17}\text{O}\), and \(^{33}\text{S}\) NMR chemical shifts calculated in a recent theoretical study\(^{232}\) (DFT/GIAO-MP2 method) match well with the experimental values. According to DFT calculations (B3LYP/6-311 + G** level), the \(\text{O}\)-protonated form is 37.0 kcal mol\(^{-1}\) more stable than the \(\text{S}\)-protonated form.\(^{232}\) The \(\text{O},\text{O}\)-diprotonated dication was calculated to be the global minimum being more stable than the \(\text{O},\text{S}\)-diprotonated ion by 20.8 kcal mol\(^{-1}\). Interestingly, the \(\text{O},\text{O}\) and \(\text{S},\text{O}\)-dimethylated dications were found to be isoenergetic. Diaryl sulfoxides were also shown to be protonated at the oxygen in Magic Acid with the exception of the parent diphenyl sulfoxide and bis(2,4,6-trifluorophenyl) sulfoxide.\(^{233,234}\) \(\text{O}\)-Protonation was calculated to be favored over \(\text{S}\)-protonation by about 17 kcal mol\(^{-1}\).\(^{235}\) Low-temperature NMR studies indicated significant \(\pi\)-electron delocalization and, consequently, increased double-bond character of the \(\text{C}–\text{S}\) bond and, in some cases, two conformations were observed.\(^{234}\) The conformers of diphenyl sulfoxide with \textit{syn} or \textit{anti} orientation of the OH proton relative to the aromatic rings are separated by a barrier of 1.3 kcal mol\(^{-1}\).

Dimethoxyfluorosulfonium ion \(84\) has been generated from methylfluorosulfite by methylation with \(\text{CH}_3\text{F}\) under superacidic conditions\(^{236}\) [Eq. (4.63)]. A similar
O-methylation of thionyl fluoride yields ion F$_2$(MeO)S$^+$\(^{237}\). Both ions show a single deshielded methoxy resonance (\(\delta^1\)H 4.89 and 5.27, respectively).

\[
\begin{array}{c}
F = SMeO + CH_3F \xrightarrow{SbF_5-SO_2} F = SMeO MeO
\
\end{array}
\]

Minkwitz and Molsbeck\(^{238}\) have performed O-methylation of various sulfoxides to obtain the corresponding methoxysulfonium ions [Eq. (4.64)] and also reported their spectroscopic characterization (Raman and \(^1\)H, \(^{13}\)C, and \(^{19}\)F NMR).

\[
\begin{array}{c}
R' = O + MeOSO^+ MF_6^- \xrightarrow{SO_2} R' = O MeO MF_n^-
\
R, R' = F, Cl, CH_3, CF_3
\end{array}
\]

Shine and co-workers\(^{239,240}\) have reported the synthesis and full NMR characterization of a series of alkoxysulfonium ion perchlorates including ions 85 derived from cis- and trans-substituted cyclohexanols. The X-ray structural study of four salts showed that the orientation of the S–O bond is always pseudoaxial. The optically active (–)-86 ion and similar systems have been synthesized.\(^{241}\) \(^1\)H and \(^{13}\)C NMR measurements indicate that sulfur has a trigonal bipyramidal geometry due to the S–O intramolecular interaction in the axial position.

\[
\begin{array}{c}
S = O + MeOSO^+ MF_6^- \xrightarrow{SO_2} S = O MeO MF_n^-
\
R, R' = F, Cl, CH_3, CF_3
\end{array}
\]

**Sulfonium Ions with Nitrogen Ligands.** Long-lived aminofluorosulfonium ions have been prepared by ionization under superacidic conditions\(^{242,243}\) [Eq. (4.65)]. The stereochemistry of ion Me$_2$NSF$_2^+$ was studied by dynamic \(^1\)H NMR spectroscopy.
and structure 87 was established with a rotation barrier of 14.7 kcal mol\(^{-1}\) about the N–S bond.\(^{243}\)

\[
(R_2N)_mSF_{4-m} + MF_n \rightarrow (R_2N)_nSF_{3-m}^+MF_{n+1}^-
\]

(R\(_2\)N\(_m\))\text{SF}_{4-m} + MF\(_n\) \rightarrow (R\(_2\)N\(_n\))\text{SF}_{3-m}^+MF_{n+1}^-

\(m = 1–3\)

\(MF_n = \text{BF}_3, \text{PF}_5, \text{AsF}_5, \text{SbF}_5\)

87

Nucleophilic substitution of fluorine in perfluorinated sulfonium ions yields the corresponding aminosulfonium ions when reacted with Me\(_3\)SiNMe\(_2\) [Eq. (4.66)]. Crystal structure analysis of CF\(_3\)S(NMe\(_2\))\(_2\)\(^+\), (CF\(_3\))\(_2\)SNMe\(_2\)\(^+\), and F\(_2\)SNMe\(_2\)\(^+\) hexa-fluoroarsenates gives similar S–N bond distances (1.605, 1.578, and 1.535 \(\text{Å}\), respectively).\(^{215,244}\)

\[
\begin{align*}

R &= \text{CF}_3, (\text{CF}_3)\text{CF}
\end{align*}
\]

Studies by Olah et al.\(^{245}\) have shown that due to its ambident character the NO\(_2\)\(^+\) ion when reacting with sulfides gives both S-nitro- and S-nitritiosulfonium ions (88 and 89). Ions 88 are irreversibly transformed into 89 upon raising the temperature. The corresponding dimethyl species were detected by \(^{13}\)C NMR spectroscopy (two methyl resonances at \(\delta^{13}\)C 25.2 and 34.5). Dialkyl- and diarylsulfoxides also yield two ions reacting with NO\(_2\)\(^+\) (90 and 91).\(^{246}\) Again, two methyl resonances were observed in a controlled reaction of dimethylsulfoxide. The intensity of the resonance at \(\delta^{13}\)C 35.4 slowly decreased upon raising the temperature from \(-60\) to \(-20\)\(^\circ\)C and disappeared after 4–5 h, whereas the resonance at \(\delta^{13}\)C 42.4 remained unchanged.
Sulfonium Ions with Sulfur Ligands. Steudel and co-workers\textsuperscript{247} prepared and characterized the Me\textsubscript{2}SSMe\textsuperscript{+}SbCl\textsubscript{6}\textsuperscript{−} salt, the sulfur analog of ion 49. The ion has Cs symmetry and the sole methyl group on S(2) bisects the angle formed by the other two methyl groups on S(1). They also determined the crystal structure of cation (MeS)\textsubscript{3}\textsuperscript{+} (92). The chain-end methyl groups were shown to occupy trans position with respect to the plane defined by the three sulfur atoms. The S–S–S–C torsion angle is 90.5° and the S–S bond distances (2.041 and 2.056 Å) are close to the single bond lengths.

Trimercaptosulfonium salts were prepared by reacting Cl\textsubscript{3}S\textsuperscript{+} salts with excess H\textsubscript{2}S\textsuperscript{248} [Eq. (4.67)]. According to calculation, the pyramidal structure of C\textsubscript{3v} symmetry is the energy minimum structure with the S–H bonds pointing toward the top of the pyramid. The corresponding dimercapto(methyl)sulfonium salts were also synthesized in an analogous way.\textsuperscript{249} The products were transformed into chlorothio derivatives [Eq. (4.68)].

\end{equation}

\begin{equation}
\text{HS}^{+}\text{RMX}_{6}^{-} + \text{Cl}_{2} \xrightarrow{-70 \text{ or } -78^\circ\text{C}} \text{ClIS}^{+}\text{R'MX}_{6}^{-} \quad (4.68)
\end{equation}

Minkwitz et al.\textsuperscript{250} have obtained tris(methylthio)sulfonium hexafluoroantimonate in a solventless reaction at low temperature [Eq. (4.69)] and characterized the salt by Raman, IR, \textsuperscript{1}H and \textsuperscript{13}C NMR to spectroscopy. The salt is stable below 10°C but decomposes in SO\textsubscript{2} solution at −45°C with rapid elimination of sulfur. It possesses C\textsubscript{3} symmetry with a pyramidal trithiosulfonium unit and the methyl groups point to the central sulfur atom (\textit{ab initio} calculations).

\begin{equation}
\text{H}_{3}\text{S}^{+}\text{SbF}_{6}^{-} + 3 \text{CH}_{3}\text{SCl} \xrightarrow{-60^\circ\text{C}} \text{CH}_{3}\text{S}^{+}\text{SCH}_{3}\text{SbF}_{6}^{-} + 3 \text{HCl} \quad (4.69)
\end{equation}
Substitution of chlorine in ion $\text{MeSCl}_2^+$ results in the formation of dithio-substituted methylsulfonium ions$^{251}$ [Eq. (4.70)]. X-ray structure determination of the $(\text{MeS})_2 \text{SMe}^+ \text{AsF}_6^-$ salt gives $\text{S-S}$ bond distances of 2.048 and 2.054 Å and a $\text{S-S-S}$ bond angle of 107.6°.

\[
\text{MeS}^+ \text{Me} \text{MX}_6^- + 2\text{Me}_2\text{S}_2 \rightarrow -65^\circ \text{C} \quad \text{MeSCl}_2^+ \text{MX}_6^- + 2\text{Ph}_2\text{SH} \rightarrow -70^\circ \text{C} \quad \text{MX} = \text{AsF}, \text{SbCl}
\]

Sulfonium ion 93 has been prepared by treatment of the starting disulfur compound with $\text{NO}^+\text{PF}_6^-$ and the transformation was interpreted with the involvement of a dicationic species$^{252}$ [Eq. (4.71)]. Treatment of the corresponding sulfoxide with $\text{Tf}_2\text{O}$ resulted in the formation of a cyclic product ion$^{253}$ [Eq. (4.72)].

Thiosulfonium ions derived from methylation of substituted 1,2-dithianes (94a) were found to exist in undistorted chair conformation with the methyl group in axial position.$^{254}$ The phenomenon was interpreted to result from minimizing electron repulsion in orthogonal position (94b) (\textit{ab initio} calculation at STO-3G*/STO-3G level). Unlike 1,2-dithianes, methylation of 1,2-dithiolanes and substituted thianes to form the corresponding $\text{S}$-methylsulfonium hexafluorophosphate and perchlorate salts$^{255}$ is non-stereoselective.
Chemical two-electron oxidation of the corresponding 1,2-dithiin resulted in the formation of a stable solution of dication 95 (no decomposition was observed at $-18^\circ $C for months) [Eq. (4.73)]. $^1$H and $^{13}$C NMR spectra of the dication exhibited resonances at considerably lower fields compared with those of the neutral starting material suggesting aromatic stabilization. Calculated geometries (B3LYP/6-31G*) indicate a planar ring and calculated chemical shifts are in fair agreement with observed values. The related 1,4-dithiin dication was also characterized.

\[ \text{Silylated Sulfonium Ions.} \] Olah, Prakash, and co-workers have prepared silyl-substituted sulfonium ions [Eq. (4.74)] and characterized the products by multinuclear NMR spectroscopy. Calculated (DFT/IGLO) $^{13}$C and $^{29}$Si chemical shifts agree well with experimental data. The minimum energy structures of ions 96a and 96b are of $C_1$ and $C_3$ symmetry, respectively, with pyramidalization levels of 19° and 16° (pyramidalization level = out-of-plane bending angle of the central sulfur atom relative to the plane defined by its three bonding groups). A solution of ion 96a is more stable than that of ion 96b. The preparation of dimethyl(trimethylsilyl)sulfonium ion under similar conditions failed and the more stable $\text{Me}_3\text{Si}^+\text{OTf}^-$ was formed instead.

\[ \text{Aurated Sulfonium Ions.} \] Sheldrick and co-workers were the first to report the synthesis and X-ray characterization of the aurated sulfonium salt ($\text{Ph}_3\text{PAu})_3\text{S}^+\text{PF}_6^-$ and subsequently Schmidbaur et al. synthesized similar tetrafluoroborates using two approaches [Eq. (4.75)]. The aurated sulfonium cations in the solid state are pyramidal and form dimeric units (97a) or strings of dimers (97b). In contrast, 97c and 97d do not build supracationic aggregates. In cation 97c the $\text{Au}^--\text{S}^+\text{Au}$ bond angle is 90.8°, the $\text{Au}^--\text{S}$ bond distance is 3.253 Å, and the intramolecular $\text{Au}^--\text{Au}$ contact is 2.285 Å. The supramolecular structure of ions 97a and 97b results in significant distortions of the cationic structures: much smaller (as low as 80.8°) bond angles are
detected and the Au—S bonds are generally longer. The inter- and intramolecular Au···Au contacts are similar but shorter than in complex 97c.

\[
(R_3PAu)_3O^+BF_4^- + (Me_3Si)_2S \rightarrow (R_3PAu)_3S^+BF_4^- \rightarrow R_3PAu^+BF_4^- + (Me_3Si)_2S
\]

97 \( a \) \( R = Me \)  
\( b \) \( R = MePh \)  
\( c \) \( R = isoPr \)  
\( d \) \( R = Ph \)

(4.75)

The partially aurated ion 98 has been obtained by Sladek and Schmidbaur,\textsuperscript{261} who reacted \((\text{Ph}_3\text{PAu})_3\text{O}^+\text{BF}_4^-\) with 2-methylpropane-2-thiol. Cation 98 is dimeric in the crystal with very similar Au—Au distances within and between the monomeric units indicating significant aurophilic interaction between cations.

A unique mixed-valence aurated sulfonium cation 99 has been synthesized by Laguna and co-workers\textsuperscript{262} by reacting the Au(III) precursor \([\text{(C}_6\text{F}_5)_2\text{Au(On)}}\) with \([\text{S(Au}_2\text{dppf)]\} [\text{dppf} = 1,1'-\text{bis(diphenylphosphino)ferrocene}]. The P—Au—S arrangements are close to linear (170.70–175.62°) and the S(1)—Au (III)—S(2) angle is 95.19°. The most significant feature of the cation 99, in addition to three Au(I)—Au(I) contacts, is the Au(I)—Au(III) interactions of 3.2195 and 3.3661 Å. Results of DFT calculations agree only qualitatively with experimental data.

\[
\begin{array}{c}
\text{Ph}_3\text{PAu} \\
\text{Ph}_3\text{PAu} \\
\text{S} \\
\text{tertBu BF}_4^- \\
\end{array}
\]

98

Laguna and co-workers\textsuperscript{263} have reported the synthesis and X-ray characterization of the aurated sulfonium dication \([\text{(Ph}_3\text{PAu)}_4\text{S}]^2^+\) with \([\text{S(Au}_2\text{dppf)]\} [\text{dppf} = 1,1'-\text{bis(diphenylphosphino)ferrocene}]. The P—Au—S bond angles are significantly smaller than those in the corresponding monocation \([\text{(Ph}_3\text{PAu)}_3\text{S}]^+\) (73.5–75.6° versus 80.82–87.8°\textsuperscript{119,259}), resulting in short Au—Au distances between adjacent and longer ones.
between opposite Au atoms (2.883–2.938 and 3.4 Å, respectively). There are two distinctive Au–Au–Au angles: about 75° and about 100°. Subsequently, they synthesized a variety of highly aurated sulfonium complexes [(Ar₃PAu)ₙS]^(α−2)+ and reported the X-ray structure of dication [(Ph₃PAu)₄S]^2+(ClO₄)^− with structural features similar to that of the triflate salt.²⁶⁴

Aurated dications of a different type, bissulfonium salts 100 formed from dithiols, have been reported²⁶⁵,²⁶⁶ including the systematic study by Sladek and Schmidbaur.²⁶⁷ Single-crystal X-ray diffraction study indicated that they form complicated aggregated structures.

![Image of structural formula](image_url)

### 4.2.3. Selenonium and Telluronium Ions

A great number of trialkyl(aryl) selenonium and telluronium ions are known, and their synthesis does not require the use of strong electrophilic alkylating or arylating agents.²⁶⁸,²⁶⁹ The synthesis and transformations of triorganotellurium ions have been treated in recent reviews.²⁷⁰,²⁷¹ However, acidic selenonium and telluronium ions can be obtained only under superacidic conditions.

#### 4.2.3.1. Hydridoselenonium and Hydridotelluronium Ions.

Hydrogen selenide is considerably less basic than hydrogen sulfide and, consequently, more difficult to protonate and the resulting hydridoselenonium salts are expected to be more thermolabile. Nevertheless, hydrogen selenide can be protonated by HF–BF₃ in excess HF solution²⁷² [Eq. (4.76)]. The hydridoselenonium ion 101 formed in this way at −70°C shows a singlet ¹H NMR resonance at δ¹H 5.8, deshielded by 6.1 ppm from the ¹H NMR resonance of parent H₂Se. In the ⁷⁷Se NMR spectrum, 101 is observed at δ⁷⁷Se −142 (from dimethyl selenide) with no resolvable ⁷⁷Se−¹H coupling even at −90°C.²⁷³ Methyl selenide also undergoes protonation in HF–BF₃ media to methylselenonium ion MeSeH⁺. The methylselenonium ion, however, shows ⁷⁷Se−¹H coupling in the ⁷⁷Se NMR spectrum (J⁷⁷Se−¹H = 129.5 Hz). A long-range ⁷⁷Se–methyl proton coupling of 8.9 Hz is also observed²⁷³.

\[
\text{H}_2\text{Se} + \text{HF} + \text{BF}_3 \rightarrow \text{H}_2\text{Se}^+\text{BF}_4^- \quad (4.76)
\]

101

The HF–SbF₅ superacid has been used to prepare the H₃Se⁺SbF₆⁻ salt [Eq. (4.77)] and the perdeuteriated derivative.²⁷⁴ The salt is stable at 195 K but decomposes within minutes at 213 K to reform the starting materials.

\[
\text{H}_2\text{Se} + \text{HF} + \text{SbF}_6 \quad 195 \text{ K} \rightarrow \text{H}_3\text{Se}^+\text{SbF}_6^- \quad (4.77)
\]
The parent hydrotelluronium ion $H_3Te^+$ could not be observed in superacid solution of hydrogen telluride, under conditions where the selenonium ion is observed.

### 4.2.3.2. Acidic Selenonium and Telluronium Ions

Alkyl selenides are much more stable to oxidation than hydrogen selenide, and they can be protonated in $HSO_3F–SbF_5–SO_2$ solution$^{272}$ [Eq. (4.78)]. The dimethylselenonium ion $Me_2SeH^+$ (protonated dimethyl selenide) shows in its $^1H$ NMR spectrum the methyl doublet at $\delta^1H 2.96 (J = 7.0 \text{ Hz})$ and the $SeH$ septet at $\delta^1H 4.50 (J = 7.0 \text{ Hz})$. A double irradiation experiment showed that the doublet and septet are coupled. The $^1H$ NMR spectrum also shows an unidentified small doublet at $\delta^1H 3.50$ and a singlet at $\delta^1H 3.80$ for the $Me_2Se–SbF_5$ complex. The diethylselenonium ion shows the methyl triplet at $\delta^1H 2.00$, the methylene quintet at $\delta^1H 3.77$, and the $SeH$ quintet at $\delta^1H 4.40$. The $^{13}C$ and $^{77}Se$ NMR data of these two ions agree well with $^1H$ NMR results. The acidic, secondary alkylselenonium ions are remarkably stable. The $^1H$ NMR spectra show no significant change from $-60^\circ\text{C}$ to $+65^\circ\text{C}$.

$$RSeR \xrightarrow{HSO_3F–SbF_5–SO_2} R^+ \begin{array}{c} \downarrow \ Se\downarrow H \\ \downarrow \ R \end{array}$$  \tag{4.78}$$

R = Me, Et

Alkyl tellurides in $HSO_3F–SbF_5–SO_2$ solution at $-60^\circ\text{C}$ show deshielded alkyl proton chemical shifts (with no long-range proton coupling) as compared with the corresponding dialkyl tellurides themselves in $SO_2$. This indicates that in this medium the tellurides are probably oxidized. However, using HF–BF$_3$ in excess HF solution [Eq. (4.79)], both the $TeH^+$ proton and its coupling to secondary alkyl groups can be observed$^{272}$

$$R_2Te + HF + BF_3 \rightarrow R^+ \begin{array}{c} \downarrow \ Te\downarrow H \downarrow BF_4^- \\ \downarrow \ R \end{array}$$ \tag{4.79}$$

R = Me, Et, n-Bu

The dimethyltelluronium ion $Me_2TeH^+$ (protonated dimethyl telluride) shows the methyl doublet at $\delta^1H 2.7 (J = 7 \text{ Hz})$ and the septet at $\delta^1H 1.6$. Similarly, the diethyltelluronium ion $Et_2TeH^+$ (protonated diethyl telluride) shows the methyl triplet at $\delta^1H 1.9$, the methylene quintet at $\delta^1H 3.4$, and the multiplet, partially overlapping the methyl triplet at $\delta^1H 1.6$.

The proton on selenium in selenonium ions and on tellurium in telluronium ions is considerably more shielded than the proton on oxygen in the related oxonium ions ($\delta 7.88–9.21$) and the proton on sulfur in the corresponding sulfonium ions ($\delta 5.80–6.52$). There is a consistent trend of increasing shielding going from related oxonium to sulfonium to selenium to telluronium ions (which is particularly significant when considering the directly observed protons on heteroatoms). Charge delocalization and shielding by increasingly heavier atoms is thus indicated.
Laali et al. also observed that the $^{77}\text{Se}$ chemical shifts in the long-lived acidic selenonium ions $\text{R}_2\text{SeH}^+$ (Me = $\delta^{77}\text{Se}$ 343, Et = $\delta^{77}\text{Se}$ 399) are more deshielded than that in the corresponding $\text{R}_2\text{Se} \rightarrow \text{SbF}_5$ donor–acceptor complexes (Me = $\delta^{77}\text{Se}$ 258, Et = $\delta^{77}\text{Se}$ 317). The $^{13}\text{C}$ chemical shifts, in turn, show an opposite trend; that is, the $\alpha$-methyl carbon is more deshielded in the donor–acceptor complexes than in the ions.

### 4.2.3.3. Tertiary Selenonium and Telluronium Ions.

Triaalkylselenonium fluorosulfates are conveniently prepared by the reaction of dialkyl selenide and alkyl fluorosulfates, using 1,1,2-trichlorotrifluoroethane as the reaction medium [Eq. (4.80)]. Trimethylseleninium fluorosulfate $\textbf{102a}$ thus prepared is a stable, white solid (mp = 83–85°C), which, when dissolved in liquid sulfur dioxide, exhibits a singlet proton NMR absorption at $\delta^1\text{H}$ 2.7. Triethylselenonium fluorosulfate $\textbf{102b}$ has also been prepared in the same way. It is also a stable, white solid (mp = 25–28°C). When dissolved in liquid sulfur dioxide, $\textbf{102b}$ shows the methylene protons at $\delta^1\text{H}$ 3.2 (quartet) and the methyl protons at $\delta^1\text{H}$ 1.4 (triplet).

$$\text{RSeR} + \text{ROSO}_2\text{F} \xrightarrow{\text{Cl_2FCCF}_2\text{Cl}} \text{R}_3\text{Se}^+\text{FSO}_3^- \quad (4.80)$$

Further examples of alkylation of selenides are shown in Eqs. (4.81) and (4.82).

$$\text{Ph}_2\text{Se} + \text{RCH}_2\text{X} \xrightarrow{\text{AgBF}_4} \text{PhSe}^+\text{CH}_2\text{R BF}_4^- \quad (4.81)$$

$$\text{ArSeR} + \text{Me}_3\text{O}^+\text{BF}_4^- \xrightarrow{\text{CH}_3\text{CN}} \text{ArSe}^-\text{Me Y}^- \quad (4.82)$$

Methylation of trifluoromethylphenylselenide under conditions shown in Eq. (4.81) was successfully employed in the synthesis of $\text{Me(CF}_3\text{)PhSe}^+\text{BF}_4^-$. The cyclization methods described in Eq. 4.45 have also been used to prepare analogous Se and Te derivatives [Eq. (4.83)].
Kataoka and co-workers have developed methods to obtain alkynyl- and alkenyl-selenonium ions \(^{279,280}\) [Eq. (4.84)] and allenylselenonium triflate derivatives.\(^{281}\)

\[
\begin{align*}
\text{Ph} & \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \ quad
and $^{125}$Te chemical shifts were shown to increase with the increasing size of the alkyl groups. The $^{13}$C NMR chemical shifts of carbons directly attached to the heavy atom are significantly shielded, showing the tendency of increasing shielding $\text{Me}_3\text{S}^+$ ($\delta^{13}$C 27.20) $< \text{Me}_3\text{Se}^+$ ($\delta^{13}$C 21.78) $< \text{Me}_3\text{Te}^+$ ($\delta^{13}$C 3.76).

A wide variety of synthetic procedures have been developed to synthesize telluronium ions from disubstituted tellurides. $^{271}$ Naumann and Tyrra $^{285,286}$ have prepared ion $^{104}$ using various approaches [Eq. (4.88)] whereas du Mont and co-workers $^{287}$ obtained the trimesityltelluronium cation $^{105}$ [Eq. (4.89)]. Cation $^{105}$ has a propeller-like conformation with $\text{C}/\text{C}_0\text{Te}/\text{C}_0\text{C}$ angles close to tetrahedral (104.4–109.3°). The triflate salt of ion $^{104}$ has a distorted $\psi$-trigonal bipyramidal geometry and the $\text{C}/\text{C}_0\text{Te}/\text{C}_0\text{C}$ angles (91.1–106.1°) are somewhat different from those in ion $^{105}$.

Diaryltellurium difluorides also serve as convenient and versatile starting materials to obtain various telluronium tetrafluoroborates $^{288}$ (Scheme 4.9). The tellurium atom in cation $^{106}$ (Ar = Ph, R = tert-Bu) has a distorted pyramidal geometry. The observed Te–C bond distances (2.108–2.129 Å) are close to those reported for other telluronium ions. There is a weak nonbonding interaction between Te and O manifested in the lower IR absorption of C = O (1678 cm$^{-1}$). The $^{125}$Te NMR chemical shifts in the range $\delta^{125}$Te 645–755 indicate the onium ion character of the central tellurium atom. Ph$_2$TeF$_2$ also reacts with aryl- and alkenylboronic acids in the presence of BF$_3$·OEt$_2$ to yield the corresponding aryl- or vinyl-substituted telluronium tetrafluoroborates. $^{289}$

1-Alkynylphenyliodonium tetrafluoroborates selectively transfer the unsaturated group to diphenyl chalcogens to form 1-alkynyl(diphenyln)onium ions $^{290}$

\[
\begin{align*}
\text{Scheme 4.9}
\end{align*}
\]
Analogous reactions can be performed with vinyl derivatives to obtain 1-vinylidiphenylonium ions. \(^{291}\)

\end{align*}
\]

\(\text{Eq. (4.90)}\)

Hypervalent pentaphenyltelluronium salts obtained by Akiba and co-workers\(^{292}\) [Eq. (4.91)] were shown by X-ray crystal structure analysis to have unusual square pyramidal geometry. The Te–C\(_{\text{apical}}\) bond lengths (2.101–2.125 Å) are significantly shorter than the four basal Te–C bond distances (2.174–2.214 Å). The \(^{125}\text{Te} \) NMR spectra of the three salts show almost identical chemical shifts (\(\delta^{125}\text{Te} 659.0–659.9\)) which are upfield from that of Ph\(_3\)Te\(^{+}\) (\(\delta^{125}\text{Te} 753.0\)).

\[
\begin{align*}
\text{Ph}_5\text{TeCl} & \xrightarrow{\text{AgClO}_4 \text{ or } \text{AgOTf}} \text{Ag} \quad \text{NaTFPB or } \text{LiB(C}_6\text{F}_5)_4 \\
\text{CH}_2\text{Cl}_2 \text{ or THF} & \quad \text{–78°C to RT} \quad \text{X = ClO}_4, \text{TFPB, B(C}_6\text{F}_5)_4 \\
\text{Ph}_5\text{Te}^+ \text{X}^- & \quad \text{Eq. (4.91)}
\end{align*}
\]

The unusual telluronium dication analogous to 79 [see Eq. (4.47)] has also been prepared by Furukawa and Sato.\(^{197,198}\) The \(^1\text{H} \) and \(^{13}\text{C} \) NMR spectra are consistent with those of dication 79. The X-ray crystallographic analysis of the triflate salt indicates, however, a nearly hexagonal structure for the telluronium dication. This results from the strong interaction of the anions with the Te center forming a hexavalent structure.

Gillespie and coworkers obtained the compound Ph\(_2\)Se\(_6^+\)AsF\(_6^-\)·SO\(_2\).\(^{293}\) The cation 107 consists of a six-membered selenium ring in a boat conformation with the phenyl rings at opposite corners. The average Se–Se bond length of 2.416 Å is typical for selenium dications. The distance across the top of the boat is 3.550 Å, which is smaller than the sum of the van der Waals radii (4.00 Å) indicating a weak intracationic interaction.

![107]

du Mont and co-workers\(^{287}\) have prepared cations 108 containing Te–Se (108a) or Te–Te (108b) moiety [Eq. (4.92)]. The X-ray crystal structure of the ions shows that
the coordination geometry of all chalcogen atoms is pseudo-trigonal-bipyramidal, when secondary M–F contacts are taken into consideration. The ions are dimeric in the solid state with a bridging SbF$_6^-$ unit. Te–F and Se–F interactions weaken the Te–Se and Te–Te bonds (Te–Se bond length = 2.5755 Å, Te–Te bond length = 2.7645 Å). The ions, therefore, can be regarded as MesTe$^+$ and C$_6$F$_5$Se$^+$ cations stabilized by the coordinating Lewis base Mes$_2$Te.

\[
(C_6F_5)_2Se_2 + Mes_2Te + Br_2 + 2AgSbF_6 \rightarrow [Mes_2TeXAr]^+ SbF_6^-
\]

\[\text{108 a } X = \text{Se, } Ar = C_6F_5 \]

\[\text{108 b } X = \text{Te, } Ar = \text{Mes}\]

\[\text{(4.92)}\]

4.2.3.4. Haloselenonium and Halotelluronium Ions. Oxidative chlorination of Se and Te in the presence of AsF$_3$/AlCl$_3$ was used by Kolditz and Schäfer to synthesize SeCl$_3^+$AsF$_6^-$ and TeCl$_3^+$AsF$_6^-$.\textsuperscript{203} F$_3$Se$^+$ salts with a variety of anions were prepared by Peacock\textsuperscript{294} and Bartlett and Robinson.\textsuperscript{199} The ionic nature of these salts was first demonstrated by Edwards and Jones,\textsuperscript{295} who performed X-ray crystal structure analysis of TeF$_3^+$Nb$_2$F$_{11}^-$ to show substantial interaction between the ions through fluorine bridging. Later, Gillespie and Whitla\textsuperscript{296} arrived at a similar conclusion on the basis of conductometric, cryoscopic, vibrational, and NMR spectroscopic measurements with SeF$_3^+$MF$_6^-$ (M = Sb, As, Nb, Ta) and SeF$_3^+$BF$_4^-$ adducts.

Gillespie and Whitla\textsuperscript{297} also studied the SF$_4$SO$_3$ system with a variety of techniques (IR, Raman, $^{19}$F NMR, conductivity and cryoscopic measurements). In the solid and molten states the polymeric fluorosulfate bridged structure \textbf{109} exists, whereas in dilute solution the cyclic dimer \textbf{110} is the predominant species. A comparison of the $^{19}$F NMR chemical shifts of F$_3$S$^+$ and F$_3$Se$^+$ shows that fluorines bonded to Se$^+$ (δ$^{19}$F +9.6 from CFCI$_3$) are about 21 ppm shielded compared to fluorines on S$^+$ (δ$^{19}$F +30.5) indicating charge delocalization and shielding by the heavier atom.\textsuperscript{169} This observation is similar to that found for trialkylonium salts.
Subsequently, all Se and Te trihalide cations were prepared. X-ray single-crystal characterization of hexafluoroarsenate and hexafluoroantimonate salts shows that these cations, similar to the corresponding SX$_3^{+}$ cations, have trigonal pyramidal geometry and the MX$_3^{+}$ units are linked to the anions via M–F interactions. An interesting feature of the crystal structure of the hemisolvate TeI$_3^{+}$AsF$_6^{-}$/SO$_2$ is the pairwise association of the TeI$_3^{+}$ ions facing each other with the I atoms and forming large voids. This results in significantly lower density in comparison to the unsolvated salt. A computational study of SeX$_3^{+}$ ions (X = Cl, Br, I) and $^{77}$Se chemical shifts, along with the first solid-state FT–Raman spectrum of SeI$_3^{+}$AsF$_6^{-}$, has been reported. The interesting salt [(Cl$_3$Te–F–TeCl)$_3$$^{+}$] [Sb(OTeF$_5$)$_6$]$^{-}$ contains isolated cations and anions. The cation has two pseudo-bipyramidal Cl$_3$TeF(lone pair) units bridged centrosymmetrically by fluorine. Each tellurium has two shorter and one longer additional fluorine contacts.

4.2.3.5. Aurated Selenonium and Telluronium Ions. The crystal structures of [(Ph$_3$PAu)$_3$Se]$^{+}$PF$_6^{-}$ prepared by Sheldrick and co-workers and [(Ph$_3$PAu)$_3$Te]$^{+}$BF$_4^{-}$ obtained by Angermaier and Schmidbaur according to Eq. (4.93) have been determined. The Au–Te–Au angles in the Au$_3$Te pyramids are all much smaller than 90° (72.6–84.7°), resulting in Au–Au distances of 3.074–3.515 Å, which are considered to be bonding contacts. The cations are associated to dimers through short intermolecular Au–Au contacts in the same range. When the tellurium reagent was reacted with four equivalents of Ph$_3$PAu$^{+}$BF$_4^{-}$, the tetranuclear dication [(Ph$_3$PAu)$_4$Te]$^{2+}$ was obtained and assumed to have a pyramidal geometry.

\[
\text{(tert-BuMe}_2\text{Si)}_2\text{Te} + \text{(Ph}_3\text{PAu)}_3\text{O}^+\text{BF}_4^- \xrightarrow{\text{CH}_2\text{Cl}_2, \text{THF}, -78^\circ\text{C}} \text{[(Ph}_3\text{PAu)}_3\text{Te}]^+\text{BF}_4^- - \text{(tert-BuMe}_2\text{Si)}_2\text{O} 
\]

(4.93)

Laguna and co-workers have succeeded in preparing the [(Ph$_3$PAu)$_4$Se]$^{2+}$ dication 111, which crystallizes with two moles of dichloromethane and isostructural with the corresponding sulfur salts [(Ph$_3$PAu)$_4$S]$^{2+}$ (Y$^-$)$_2$ (Y = ClO$_4$, TfO) discussed above. In the tetragonal pyramidal framework, Se occupies the apical position. The base of the pyramid is not exactly coplanar but has a flattened butterfly form with a hinge angle of 27° about diagonal Au atoms. Au–Au distances between adjacent Au
atoms (2.8959–2.9605 Å) and opposite Au atoms (3.6 and 4.5 Å) are longer than those in the sulfur analogs.

4.2.3.6. Polychalcogen Dications. The first disulfonium dication derived from 1,5-dithiacyclooctane was prepared by Musker et al.\textsuperscript{307,308} [Eq. (4.94)] and subsequently Furukawa and co-workers\textsuperscript{309,310} reported the synthesis and crystal structure of dication 112. Dication 112 was prepared by reacting the corresponding monosulfoxide with (TfO)\textsubscript{2}O, which is a general method for the synthesis of analogous dichalcogen dications.\textsuperscript{311} In the crystals, there are two independent dications with slightly different characteristics. The S—C bonds (1.828–1.842 Å) are slightly longer, whereas the C—C bonds are shorter (1.509–1.527 Å) than the corresponding normal single bonds. The C—S—C bond angles are 104.1° and 104.6°. The eight-membered ring has a distorted C\textsubscript{2} chair–chair conformation. Four energy-minimum structures were located by \textit{ab initio} studies (RFH/3-21G*).\textsuperscript{312} In three structures, the lone electron pairs of the sulfur atoms have \textit{cis} configuration and all three are much more stable (by about 27–28 kcal mol\textsuperscript{-1}) than the structure with the \textit{trans} arrangement. The related dications 113 could be characterized by NMR spectroscopy.\textsuperscript{313,314} An \textit{ab initio} molecular orbital study was performed on dimeric dication 114.\textsuperscript{315} Disulfonium dications are presumed intermediates in organic transformations.\textsuperscript{316}

\begin{align*}
\text{(H}_2\text{C})_n\text{S}
&\text{S} \quad \text{(CH}_2\text{)}_n \quad + \quad \text{2 NO}^+\text{BF}_4^- \\
&\text{n} = 1, 2 \\
\text{MeCN} \\
\quad \text{2 NO} \\
&\text{MeCN} \\
&\text{2 BF}_4^- \\
\quad \text{(H}_2\text{C})_n\text{S} \quad \text{S} \quad \text{(CH}_2\text{)}_n \quad \text{2 BF}_4^- \\
&\text{n} = 1, 2 \\
\end{align*}

\text{(4.94)}
Furukawa and coworkers have also studied dications with a Se–Se unit. Dication 115 was generated by two-electron oxidation with NO\(^+\)PF\(_6^-\) [Eq. (4.95)].\(^{317}\) Computational studies of the isomeric structures have led to the same conclusions as already discussed above for disulfonylum dication 112. The analogous ditellurium dication (BF\(_4^-\) and PF\(_6^-\) salts) has also been prepared.\(^{318}\)

\[
\begin{array}{c}
\text{Se} & \text{Se} \\
\text{Se} & \text{Se}
\end{array}
+ 2\text{NO}^+\text{PF}_6^- \xrightarrow{\text{CH}_2\text{Cl}_2, \text{MeCN} \quad -78^\circ\text{C}}
\begin{array}{c}
\text{Se} & \text{Se} \\
\text{Se} & \text{Se}
\end{array} \quad 2\text{PF}_6^-
\] (4.95)

Minkwitz et al.\(^{319}\) have obtained dications 116 in the reactions of Me\(_2\)SH\(^+\) and Me\(_2\)SSH\(^+\) with SCl\(_2\) and S\(_2\)Cl\(_2\), respectively, and reported spectroscopic characterization (IR, X-ray, and \(^1\text{H} \) and \(^{13}\text{C} \) NMR).

\[
\text{Me}_2\text{S} - \text{S} \quad - \quad \text{SMe}_2
\]

\(n = 1-3\)

116

Disulfonylum dicatonic species with the participation of hypervalent Se (117) or Te (118) atom have been described.\(^{316,320}\) The \(^{77}\text{Se} \) NMR spectrum of the dihexafluorophosphate salt of dication 117 shows a single peak at \(\delta^{77}\text{Se} 946.7\) characteristic of selenuranes.\(^{321}\) The \(^{125}\text{Te} \) NMR chemical shifts for ions 118 are in the range \(\delta^{125}\text{Te} 1327.3-1343.\)^\(^{322,323}\) X-ray structure determination of the ditriflate salt of 118 \((R = \text{Ph})\) showed that the Te atom has a distorted trigonal bipyramidal geometry with two apical Te–S bonds and two equatorial Te–C bonds, with the lone electron pair occupying the third equatorial position. NMR spectral characteristics indicate that the ions have \textit{cis–trans} or \textit{trans–cis} configuration [the phenyl group attached to S(1) or S(3) is \textit{trans} to the other two phenyl groups]; that is, a racemic mixture exists. According to \textit{ab initio} calculations (RHF/3-21G* level), the total positive charge, located exclusively on the chalcogen atoms, is +2.578 [S(1) = +0.483, S(2) = +0.495, Te = +1.600], that is, larger than 2, which is attributed to the polarization of the Te–C and S–C bonds.

Other dications with three chalcogen atoms have also been studied.\(^{316}\) When the tris-selenide precursor was oxidized with NO\(^+\)PF\(_6^-\), the twin-chair conformer changed to the more rigid twin boat conformer 119 [Eq. (4.96)].\(^{321}\) This was evidenced
by a change in the $^1$H NMR resonance of the benzylic protons ($\delta^1$H 3.88 and 5.33 versus $\delta^1$H 4.07 and 4.59). The crystal structure analysis also supports this conclusion. Dication 119 has an almost linear Se-Se-Se bond (Se-Se-Se bond angle = 170.21°) with a C-Se(2)-C bond angle of 95.6°. The Se(2) atom has a distorted trigonal bipyramidal configuration with two apical Se-Se bonds and two equatorial Se-C bonds, with the lone pair occupying the third equatorial position. Se(2) carries a charge of +1.020, whereas the charges on the other two Se atoms are +0.701. The analogous O-Se-Se dication, the only example with participation of oxygen, has very similar structural characteristics.

The X-ray structure of dication 120 exhibits features very similar to those of the analogous dication 118 (R = Ph). Treatment of bis(4-methylphenyl)telluride with NO$^+$BF$_4^-$ or TfO$_2$ has afforded dication 121 with NO or O$_2$ as the oxygen source. The ions are dimeric in the solid state and the anions interact with the Te atoms through their O atoms. The Te-O contacts are considerably shorter than the sum of the van der Waals radii of the two atoms (2.64–2.98 Å versus 3.60 Å). The Te atoms have pseudo-octahedral geometry.

### 4.2.4. Halonium Ions

Organic halogen cations—that is, halonium ions of acyclic (open-chain) (122) or cyclic (123) nature—have gained increasing significance, both as reaction intermediates and as preparative reagents. They are related to oxonium ions in reactivity but offer much more selectivity. Halogen atoms that form organic halonium ions are chlorine, bromine, and iodine. To date, no stable organic fluoronium ion has been prepared or characterized. A comprehensive monograph pertaining to the chemistry
of halonium ions that covers more than 200 research publications and a review have been published.

In 1894, Hartmann and Meyer were the first to prepare a diphenyliodonium ion salt when they reacted iodosobenzene in concentrated H$_2$SO$_4$ and obtained para-iodophenylphenyliodonium bisulfate. Diphenyliodonium ions have since been studied by various research groups, most notably by Nesmeyanov and Beringer since 1950. Diaryl bromonium and -chloronium ions, although considerably less stable and much less investigated, were also prepared in the 1950s by Nesmeyanov and co-workers. Iodonium ions, which are useful reagents and synthons in organic synthesis and frequently characterized as organic polyvalent iodine(III) compounds, have been extensively studied.

Open-chain (acyclic) dialkylhalonium ions of the type R$_2$X$_+$ (X = Cl, Br, I) were unknown until the 1960s, as were alkylarylhalonium ions (ArRX$_+$). Realization of their possible role as intermediates in alkylation reactions of haloalkanes and -arenes has followed their preparation and study.

One of the most daring proposals of an organic reaction mechanism of its time was made in 1937 by Roberts and Kimball, who suggested that the observed trans stereospecificity of bromine addition to alkenes is a consequence of intermediate bridged bromonium ion formation. The brief original publication suggested the actual structure of the ion is undoubtedly intermediate between 124 and 125. Structure 124 was not intended to represent a conventional free carbocation, however. Since the two carbons in either structure are joined by a single bond and by a halogen bridge, free rotation is not to be expected. A clear description of the difference in bonding between carbon and bromine in 124 and 125 was not given.

The bromonium ion concept was quickly used by other investigators to account for stereospecific transformation of alkenes, notably by Winstein and Lucas, but was not unanimously accepted. For example, in discussing the mechanistic concepts of bromonium ion formation, Gould, in his still popular text, wrote in 1959, “Although a number of additions are discussed in terms of the halogenonium-ion mechanism, the reader should bear in mind that few organic mechanisms have been accepted so widely while supported with such limited data.”
In 1967, Olah and Bollinger\textsuperscript{340} reported the first preparation and spectroscopic characterization of stable, long-lived bridged alkylenehalonium ions. This was followed by Olah and DeMember\textsuperscript{333} preparation in 1969 of the first dialkylhalonium ions. Since then the field of organic halonium ions has undergone rapid development through substantial contributions from an increasing number of investigators, notably by Peterson.\textsuperscript{341}

The halogen atom in organic halonium ions is generally bound to two carbon atoms, although in the case of acidic halonium ions—that is, protonated alkyl halides—one ligand is hydrogen.

Of the dihydrohalonium ions—that is, acidic halonium ions—only chloronium ion is characterized. HCl has been protonated to dihydrochloronium ion in HSO$_3$F–SbF$_5$ media and studied by $^1$H NMR spectroscopy.\textsuperscript{342} Christe\textsuperscript{150} managed to isolate the H$_2$Cl$^+$SbF$_6^-$ salt at low temperature, and the equilibrium molecular structure of H$_2$Cl$^+$ has been determined in the gas phase.\textsuperscript{343} Under these strongly acidic conditions, HBr and HI are readily oxidized. H$_2$F$^+$ in the condensed state cannot be considered as dihydrofluoronium ion,\textsuperscript{344} because the very electronegative fluorine atom resists acquiring positive charge. Instead, the HF solvated proton can have linear or more probably 2e–3c bonding. Mootz and Bartmann,\textsuperscript{345} however, succeeded in determining the crystal structure of the H$_2$F$^+$SbF$_6^-$ salt without being able to locate the hydrogens. Subsequently, they isolated the H$_2$F$_6^+$SbF$_6^-$ salt and found that the cation forms an unbranched chain held together by very strong hydrogen bonds, which become weaker from center to the ends.\textsuperscript{346} Both this study and an \textit{ab initio} molecular dynamic calculation\textsuperscript{347} on the formation of H$_2$F$^+$ in the HF–SbF$_5$ superacid system have concluded that the cationic species is a protonated HF chain mediating a fast proton jump process.

Both \textit{ab initio} [MP2(FU)/6-31G** level]\textsuperscript{48} and DFT (B3LYP/6-31-G** level)\textsuperscript{348} calculations have been reported for the H$_3$X$_2^+$ dications. The H$_3$Cl$^+$, H$_3$Br$^+$, and H$_3$I$^+$ dications have $C_{3v}$ symmetry and considerable kinetic barriers for deprotonation (27.4–37.9 kcal mol$^{-1}$), although deprotonation is exothermic (66.5–35.0 kcal mol$^{-1}$). In contrast, the H$_3$F$^+$ dication has a planar $D_{3h}$ structure and the dissociation energy is only 8.6 kcal mol$^{-1}$.

### 4.2.4.1. Acyclic (Open-Chain) Halonium Ions

**Alkyl- and Arylhydridohalonium Ions.** The self-condensation of alkyl halides in strongly acidic media represents a convenient preparative route to symmetric dialkylhalonium ions \textsuperscript{127} [Eq. (4.97)]. This reaction involves hydridohalonium ions \textsuperscript{126} as intermediates that subsequently undergo nucleophilic attack by excess alkyl halide.

\[
\begin{align*}
\text{R} - \text{X} & \quad \text{H}^+ \\
\text{R} - \text{X} & \quad \text{H} \quad \xrightarrow{\text{HX}} \quad \text{R} - \text{X} \quad \text{R} \\
\text{X} = \text{Cl, Br, I} & \quad \text{126} \quad \text{127}
\end{align*}
\]
Methyl bromide and methyl iodide in HSO$_3$F–SbF$_5$–SO$_2$ClF at −78°C give both dimethylhalonium ions (127, R = CH$_3$, X = Br, I) as well methylhydridohalonium ions (126, R = CH$_3$, X = Br, I). These hydridohalonium ions have been characterized by $^{13}$C NMR spectroscopy. Methyl chloride does not give methylhydridochloronium ion under similar conditions.

Protonation of methylhalonium ions to form diprotonated dications CH$_3$XH$_2^{2+}$ have been calculated (B3LYP/6-31-G** level) to occur primarily on the C–H bond to form a pentacoordinated carbon with 2e–3c bond. The halogen atoms in dications, as expected, carry more charge than in the corresponding monocations and the dications are less stable than the monocations (49.5–13.0 kcal mol$^{-1}$).

Halobenzenes do not form diarylhalonium ions under superacidic conditions. The protonation occurs either on the halogen or on the aromatic ring. Indeed, chloro- and bromobenzenes quantitatively yield the corresponding 4-halobenzenium ions (Wheland intermediates) on protonation with HSO$_3$F–SbF$_5$–SO$_2$ClF at −78°C. Iodobenzene under similar conditions gives the hydridoiodonium ion [Eq. (4.98)]. The ion 128 is rather stable and does not rearrange to ring-protonated C$_6$H$_6$I$^+$ even when the temperature is raised to −20°C.

$$\text{C}_{6}H_{6}I^+ \quad (4.98)$$

Protonation of fluorobenzene in the gas phase has been studied by infrared photodissociation (IRPD) spectroscopy by Solcà and Dopfer. F-protonated fluorobenzene was formed in significant amount when protonation was carried out with CH$_3^+$. It was found to be the most stable isomer in the gas phase by quantum mechanical calculations [B3LYP/6-311G(2df,2pd) level] separated by a large energy barrier from the four Wheland intermediates. F-protonated fluorobenzene is best described as a weakly bound ion–dipole complex between the phenyl cation and HF.

Dialkylhalonium Ions. Dialkylhalonium ions were first observed as stable fluoroantimonates and characterized by Olah and DeMember in 1969. Since then, a large number of unsymmetrical and symmetrical halonium ions have been prepared. The alkylating ability as well as intermolecular exchange reactions of dialkylhalonium ions were also studied.

There are two general methods for the preparation of dialkylhalonium ions. (i) The reaction of excess primary and secondary alkyl halides with SbF$_5$–SO$_2$ [Eq. (4.99)], anhydrous fluoroantimonic acid (HF–SbF$_5$) [Eq. (4.100)], or anhydrous silver hexafluoroantimonate (or related complex fluoro silver salts) in SO$_2$ solution [Eq. (4.101)]. (ii) The alkylation of alkyl halides with methyl or ethyl fluoroantimonate (or alkylcarbenium fluoroantimonates) in SO$_2$ solution [Eq. (4.102)]. The first method is only suitable for the preparation of symmetrical dialkylhalonium ions,
whereas the second method can be used for both symmetrical and unsymmetrical dialkylhalonium ions. Additional methods for the preparation of dialkylhalonium ions are also available, but these methods generally have less practical value.

\[
2RX + H^+\text{SbF}_6^- \rightarrow RXR \text{SbF}_6^- + HX \quad (4.100)
\]

\[
2RX + Ag^+\text{SbF}_6^- \rightarrow RXR \text{SbF}_6^- + AgX \quad (4.101)
\]

\[
R'X + R^+\text{SbF}_6^- \rightarrow R'XR \text{SbF}_6^- \quad (4.102)
\]

Ions 129–133 are some of the representative dialkylhalonium ions that have been prepared and characterized.\(^{399}\) (Trimethylsilyl)methylhalonium ions 134 have also been obtained under stable ion conditions and characterized by \(^1\)H, \(^{13}\)C, and \(^{29}\)Si NMR spectroscopy.\(^{67}\) The Raman and IR spectroscopic studies of dimethylhalonium ions 129 seem to indicate that these species exist in a bent conformation.

\[

129 & \\
130 & \\
131 & \\
132 & \\
133 & \\
134 & \\
\end{align*}
\]

X = Cl, Br, I

Minkwitz and Gerhard\(^{355}\) have reported the synthesis of the AsF\(_6^-\) and Sb\(_2\)F\(_{11}^-\) salts of cation 129 (X = Br) by reacting bromine with CH\(_3\)OSO\(^+\)MF\(_6^-\) (M = As, Sb). In the analogous reaction with iodine, the salts (CH\(_3\)I\(_2\))\(_n\)^{n+}(MF\(_6^-\))\(_n\) (M = As, Sb) of unknown structure were isolated. They also succeeded in methylating CF\(_3\)I to obtain cation 135 [Eq. (4.103)] but failed to prepare the analogous bromonium compound.\(^{356}\)

\[
\begin{align*}
\text{CF}_3^+ + \text{CH}_3^- + \text{MF}_5^- \rightarrow \text{CF}_3^+ \text{CH}_3 \text{MF}_6^- \quad (4.103)
\end{align*}
\]
Even dicyclopentylbromonium ion \(136\) has been prepared\(^{357}\) by the ionization of cyclopentyl bromide in \(\text{SbF}_5\)-\(\text{SO}_2\text{ClF}\) solution at low temperature. Also a series of alkylcyclopentylhalonium ions \(137\) and \(138\) has been studied.\(^{357}\)

\[
\begin{align*}
\text{136} & \quad \text{Br}^+ \\
\text{137} & \quad \begin{array}{c} \text{Cl}^+ \\
\text{R} = \text{Me, isoPr}
\end{array} \\
\text{138} & \quad \begin{array}{c} \text{X} = \text{Br, I} \\
\text{R} = \text{Me, Et, isoPr}
\end{array}
\end{align*}
\]

Alkylvinylhalonium ions \(139\), which are stable only below \(-90^\circ\text{C}\), have also been investigated.\(^{358}\)

\[
\begin{align*}
\text{139} & \quad \begin{array}{c} \text{X} = \text{Cl, Br} \\
\text{R} = \text{Me, Et}
\end{array}
\end{align*}
\]

Cubylhalonium ions, the first stable acyclic tertiary halonium ions, have been prepared by Olah, Prakash, and co-workers.\(^{359,360}\) Methyleneation of 1,4-dihalocubanes with \(\text{CH}_3\text{F–SbF}_5\) at \(-60^\circ\text{C}\) gave the ions \(140\text{a}\) and \(140\text{b}\), which could be identified unequivocally on the basis of their \(^{13}\text{C}\) NMR spectra. Assignments for \(140\text{c}\), however, were inconclusive due to the formation of unidentified products. Attempts to prepare the corresponding monosubstituted analogs \(141\) in a similar way were unsuccessful. This, however, is not surprising considering the fact that halonium ions are known to localize most of their charge on the halogen atoms.

\[
\begin{align*}
\text{140} & \quad \begin{array}{c} \text{a} X = \text{I} \\
\text{b} X = \text{Br} \\
\text{c} X = \text{Cl}
\end{array}
\end{align*}
\]

Stang and co-workers\(^{361–363}\) have reported the synthesis of the triflate salts of dialkynyliodonium ions \(142\), the phenyl(cyano)iodonium ion \(143\) and the dicyanoiodonium ion \(144\).

\[
\begin{align*}
\text{142} & \quad \begin{array}{c} \text{R} = \text{tert-Bu, Me}_3\text{Si, isoPr}_3\text{Si}
\end{array} \\
\text{143} & \quad \begin{array}{c} \text{R} = \text{Me, isoPr}_3\text{Si}
\end{array} \\
\text{144} & \quad \begin{array}{c} \text{R} = \text{Me, isoPr}_3\text{Si}
\end{array}
\end{align*}
\]

In search for nonvolatile and, therefore, safer chloromethylating agents, even chloromethylhalonium ions have been synthesized.\(^{364}\) Bis(chloromethyl)
chloronium ion is formed by the ionization of dichloromethane in SbF$_5$–SO$_2$ClF at $-130^\circ$C.

Generally, the preparation of symmetrical dialkylhalonium ions is simpler and the reactions are clean. Unsymmetrical dialkylhalonium ions undergo disproportionation and alkylation (self-condensation) reactions, even at low temperatures (about $-30^\circ$C).

A qualitative measure of the stability and the sequence of reactivity of dialkylhalonium ions and their deshielding characteristics are shown in Scheme 4.10.

---

**Scheme 4.10**

Dimethylhalonium fluoroantimonates such as dimethylbromonium and -iodonium fluoroantimonates can be isolated as crystalline salts. They are stable in a dry atmosphere at room temperature, and some are now commercially available. Dimethylhalonium fluoroantimonate salts are very hygroscopic, and exposure to atmospheric moisture leads to immediate hydrolysis.

The $^1$H and $^{13}$C NMR data on dialkylhalonium ions seem to indicate the neighboring group deshielding order shown in Scheme 4.10, indicating inductive effect of the halogen atoms. Chlorine, being the smallest halogen atom in halonium ions (fluoronium ions are not known in solution), can accommodate the least amount of positive charge, whereas iodine, the largest of the halogen atoms, can accept essentially most of the charge. However, $\beta$-protons in the $^1$H NMR spectra of related homologous dialkylhalonium ions show an opposite deshielding order (Scheme 4.10) indicating that the inductive effect of the positively charged halogen atoms diminishes and the anisotropy effect of halogen atoms causes an opposite trend.

Dialkylhalonium ions are reactive alkylating agents. The alkylation of $\pi$-donor (aromatic and olefinic) and $n$-donor bases with dialkylhalonium ions has been studied. Alkylation of aromatics with dialkylhalonium ions was found to be not significantly different from conventional Friedel–Crafts alkylations, showing particular similarities in the case of alkylation with alkyl iodides. Alkylation of $n$-donor bases with dialkylhalonium salts provides a simple synthetic route to a wide variety of onium ions.

Alkylation of alkylene dihalides with methyl and ethyl fluoroantimonate (CH$_3$F–SbF$_5$–SO$_2$ and C$_2$H$_5$F–SbF$_5$–SO$_2$) gives monoalkylated halonium ions and/or dialkylated dihalonium ions, depending on the reaction conditions. Iodine shows an unusual ability to stabilize positive charge, as demonstrated by the formation of dialkyl alkylnediodonium ions [RI$^+$($\text{CH}_2$)$_n$I$^+$R, $n = 1$ to 6, R = Me, Et]. In the extreme case ($n = 1$), the two positive iodonium cation sites are separated only by a single methylene group. However, dialkyl alkylnedibromonium ions were formed only when the two positive bromines were separated by three methylene groups. In the case with four methylene groups, rearrangement to the more stable five-membered ring
tetramethylenebromonium ion takes place. Dialkyl alkylenedichloronium ions have not yet been directly observed. Consequently, the ease of formation of dialkyl alkylenedihalonium ions is similar to that of dialkylhalonium ions (Scheme 4.10).

Olah, Rasul, Prakash, and co-workers have calculated the structure and stability of protonated dimethyhalonium dications \((\text{CH}_3)_2\text{XH}^2+\) (B3LYP/6-31-G** level). Both the halogen-protonated and C–H bond protonated Br and I dications, all of \(C_2\) symmetry, were found to be energy minima on the potential energy surface. Both C–H bond protonated dications possess a pentacoordinated carbon with 2\(e\)–3\(c\) bond. The Br- and I-protonated forms are more stable than the C–H bond protonated species by 21.7 kcal mol\(^{-1}\) and 19.0 kcal mol\(^{-1}\), respectively. Of the corresponding fluorine and chlorine analogs, only the C–H bond protonated chloronium dication is an energy minimum structure.

Similar calculations of the methylated dimethyhalonium dications \((\text{CH}_3)_3\text{X}^2+\) have found the trimethylchloronium, trimethylbromonium, and trimethyliodonium dications of \(C_3v\) symmetry to be the stable minima. The fluoro analog is also an energy minimum structure but has a planar \(D_{3h}\) symmetry, a relatively long C–F bond, and a bond order of 0.53, indicating a very weak C–F bond. The order of increasing atomic charges of the halogen atoms (F = −0.27, Cl = 0.54, Br = 0.87, and I = 1.16) corresponds to the order of electronegativities (F > Cl > Br > I) and the order of sizes (I > Br > Cl > F) of the halogen atoms.

**Alkyl(aryl)halonium Ions.** Dence and Roberts attempted to prepare the cyclopropylphenyliodonium ion from phenyliodoso chloride and cyclopropyllithium \([\text{Eq. (4.104)}]\). However, they were unable to obtain the corresponding iodonium ion or any cyclopropylbenzene from the reaction mixture. Thus, the iodonium ion was not formed, even as an unstable reaction intermediate.

\[
\begin{align*}
\text{C}_6\text{H}_5\text{Cl}_2 + \text{RLi} & \rightarrow [\text{C}_6\text{H}_5\text{R}]^+ \text{Cl}^- \rightarrow \text{C}_6\text{H}_5I + \text{RI} + \text{C}_6\text{H}_5\text{Cl} + \text{RCl} \\
\text{R} &= \text{cycloC}_3\text{H}_5 \\
\end{align*}
\]

\(\text{Eq. (4.104)}\)

Perfluoroalkyliodoso trifluoroacetates react with aromatic compounds to give perfluoroalkylaryliodonium ions 145 [Eq. (4.105)].

\[
\begin{align*}
\text{RI(OOC CF}_3)_2 & \rightarrow \text{toluene, 0°C} \\
\text{R} &= \text{n-C}_3\text{F}_7, \text{n-C}_6\text{F}_{13}, \text{C}_6\text{F}_5 \\
\end{align*}
\]

\(\text{Eq. (4.105)}\)

Alkyl(aryl)halonium ions (other than perfluorinated derivatives) were first prepared by Olah and Melby. When a SO\(_2\) solution of iodonobenzene was added to a SO\(_2\) solution of the CH\(_3\)F–SbF\(_5\) complex (methyl fluoroantimonate) at \(-78^\circ\text{C}\), a clear,
slightly colored solution resulted. The $^1$H NMR spectrum of this solution at $-80^\circ$C showed in addition to the excess methyl fluoroantimonate a methyl singlet at $\delta^1$H 3.80 and a multiplet aromatic region (7.7–8.3) with a peak ratio of 3:5. The aromatic signals showed the same coupling pattern as that of iodobenzene in SO$_2$ but were deshielded by approximately 0.5 ppm. The species that accounts for the NMR data is the methylphenyliodonium ion 146-I. When bromobenzene and other aryl bromides or iodides were added in the same manner to methyl fluoroantimonate in SO$_2$, analogous spectra were obtained, indicating the formation of the corresponding methylaryl-bromonium ions [Eq. (4.106)].

$$
\begin{align*}

\text{SO}_2 \\
\text{SbF}_5 \\
\text{SbF}_6^- \\
\text{R} = \text{Me}, \text{X} = \text{I} \\
\end{align*}
$$

Likewise, the reaction of bromo- and iodoarenes with ethyl fluoroantimonate in SO$_2$ gave the corresponding ethylarylhalonium ions. The structures of all alkylarylhalonium ions prepared have been characterized by $^1$H and $^{13}$C NMR spectroscopy.

Similarly, a series of dialkylphenylenedihalonium ions such as 147–150 have been prepared and characterized. Even trihalonium ions such as 151 have been prepared. Many of the mentioned halonium ions are stable only below $-20^\circ$C and above which they undergo ring alkylation.

Ochiai et al. have developed a method for the synthesis of alkenyl(aryl)iodonium ions with the use of trimethylvinylsilanes and idosobenzene [Eq. (4.107)]. Product formation is stereospecific with retention of configuration.
Tributylstannanes have proved to be versatile reagents in the preparation of various arylidonium ions with unsaturated organic substituents. Stang and co-workers\textsuperscript{370,371} have shown that iodonium ion transfer from phenyl(cyano)iodonium triflate requiring Pd(II) and Cu(I) catalysis is a stereospecific process [Eq. (4.108)]. Stang and Zhdankin\textsuperscript{372} also prepared the bisalkenyliodonium salt \textbf{153} using the bisphenyl(alkynyl)iodonium triflate \textbf{152} [Eq. (4.109)] and have provided full spectroscopic characterization (\textsuperscript{1}H, \textsuperscript{13}C, \textsuperscript{19}F NMR, and X-ray).

Tributylstannanes have also been used in the synthesis of alkynyl(aryl)iodonium salts, including 1,3-diynyl derivatives\textsuperscript{373} and the parent member of the family, HC≡CPh\textsuperscript{+}TfO\textsuperscript{−}, which was characterized by X-ray structure analysis.\textsuperscript{374} The bisphenyliodonium triflate reagent \textbf{152} [Eq. (4.110)]\textsuperscript{372} and analogs\textsuperscript{375} were synthesized in a similar way. Alkynyltrimethylsilanes may also serve as similar useful starting materials.\textsuperscript{376,377} X-ray characterization of a variety of alkynyl(aryl)iodonium ion has been reported.\textsuperscript{332}

\textbf{Diarylhalonium Ions.} In contrast to dialkylhalonium ions and alkylarylhalonium ions, diarylhalonium ions are considerably more stable. This is particularly the case for diaryliodonium ions, which have been known for 110 years.\textsuperscript{328a} It is interesting,
however, to compare the discovery and assumed significance of these ions with that of triarylmethyl cations. The latter were discovered early in the twentieth century, but were considered only as a specific class of organic cations limited exclusively to the highly stabilized triarylmethyl systems. The general significance of carbocations as intermediates in electrophilic reactions was not recognized until many years later, when it became evident that they are intermediates in all electrophilic organic reactions. Subsequently, methods were developed to prepare practically any conceivable type of carbocations under stable ion conditions. Halonium ions represent a somewhat similar class. Diarylidonium (or, to a lesser extent, diaryl bromonium and -chloronium) ions were also for long considered a specific class of highly stabilized halonium ions. No relationship or significance was attached to these ions until many years later, when it was realized that many other types of halonium ions (such as dialkyl-, alkylaryl- and alkylenehalonium ions) can exist, and the significance of dialkylhalonium ions in electrophilic alkylation with alkyl halides was pointed out.

Diarylidonium salts (diaryl-\(\lambda^3\)-iodanes) are widely used as arylating agents. There are a number of methods available for their synthesis typically involving two or three steps.\(^{378,379}\) A recent one-pot approach, however, offers a simple and high-yielding access to unsymmetrical diarylidonium triflates using meta-chloroperbenzoic acid (mCPBA) as the oxidant\(^{380}\) [Eq. (4.111)]. Moreover, symmetrical diarylidonium salts can directly be prepared from iodine and arenes without the use of expensive aryl iodides [Eq. (4.112)].

\[\text{Ar}^1\text{I} + \text{Ar}^2\text{H} \quad \xrightarrow{\text{mCPBA, TfOH, CH}_2\text{Cl}_2, 0^\circ\text{C}} \quad \text{Ar}^1\text{Ar}^2\text{I}^+ + \text{TfO}^-\]

(4.112)
Olah et al.\textsuperscript{381,382} have studied the \textsuperscript{13}C NMR spectra of a series of diarylhalonium ions. Some of the representative diarylhalonium ions are ions 154–157.\textsuperscript{99} The synthesis of these diarylhalonium ions does not require strongly acidic conditions and thus will not be discussed here. The use of arylstannane and arylsilane precursors in the synthesis of diarylhalonium ions has been reviewed\textsuperscript{332} and the X-ray structure analysis of a number of these ions has also been reported.\textsuperscript{332} Frohn and co-workers\textsuperscript{383} have recently prepared and characterized aryl(pentafluorophenyl)iodonium tetrafluoroborates. Significant cation–anion interactions were shown to result in the formation of two arrangements in the solid state: dimers with an eight-membered ring or polymers with a zigzag chain.

4.2.4.2. Cyclic Halonium Ions

Ethylenehalonium Ions. The parent ethylenehalonium ions 158 were obtained when 1-halo-2-fluoroethanes were ionized in SbF₅–SO₂ solution at −60°C [Eq. (4.114)]. The ¹H NMR spectra of the ethylenebromonium and -iodonium ions show a singlet at δ¹H 5.53 and 5.77, respectively. Under similar experimental conditions, when 1,2-dichloroethane and 1-chloro-2-fluoroethane were treated with SbF₅–SO₂ solution, only donor–acceptor complexes 159 and 160 were formed instead of the ethylenechloronium ion.

\[
\begin{align*}
XCH_2CH_2F & \xrightarrow{\text{SbF}_5–\text{SO}_2} –60^\circ \text{C} \quad H_2C=CH_2 + \text{SbF}_6^- \\
X = \text{Br} & \quad 158-\text{Br} \\
X = \text{I} & \quad 158-\text{I}
\end{align*}
\]

Subsequently, the ethylenechloronium ion 158-CI was obtained. When, instead of SO₂, SO₂ClF was used as the solvent in the reaction of antimony pentafluoride with 1-chloro-2-fluoroethane at −80°C, a solution was obtained whose ¹H NMR spectrum consisted of these absorptions: a doublet (δ¹H 4.6, 3H, J = 6 Hz), a quartet (δ¹H 13.3, ¹H, J = 6 Hz), and a singlet (δ¹H 5.9), consistent with the formation of ethylenechloronium ion 158-CI and methylchlorocarbenium ion 161, respectively (Scheme 4.11).

\[
\begin{align*}
\text{ClCH}_2\text{CH}_2\text{F} & \xrightarrow{\text{SbF}_5–\text{SO}_2\text{ClF}} –80^\circ \text{C} \quad \text{H}_2\text{C}=\text{CH}_2 + \text{SbF}_6^- \\
\text{ClCH}_2\text{CH}_2\text{Cl} & \xrightarrow{\text{SbF}_5} \quad \text{ClCH}_2\text{CH}_2\text{Cl} + \text{SbF}_5
\end{align*}
\]

Scheme 4.11

The ethyleneiodonium ion 158-I has also been prepared by the direct iodination of ethylene using ICN–SbF₅–SO₂ClF solution [Eq. (4.115)]. However, similar reaction with either BrCN or ClCN did not give the corresponding halonium ions 158-Br and 158-CI.

\[
\begin{align*}
\text{CH}_2=\text{CH}_2 + \text{ICN} & \xrightarrow{\text{SbF}_5} –60^\circ \text{C} \quad \text{H}_2\text{C}=\text{CH}_2 + \text{SbF}_6^- \\
158-\text{I}
\end{align*}
\]
Propyleneiodonium ion **162-I** and propylenebromonium ion **162-Br** were also obtained by the ionization of 2-fluoro-1-iodopropane and 2-fluoro-1-bromopropane in SbF$_5$–SO$_2$ClF solution at $-78^\circ$C$^{386}$ [Eq. (4.116)]. The propylenechloronium ion is also known.

$$\text{CH}_3\text{CHCH}_2\text{X} \xrightarrow{\text{SbF}_5-\text{SO}_2\text{ClF}} \text{H}_3\text{C} \begin{array}{c} \text{X} \\ \text{SbF}_5^- \end{array} \quad \text{X = Br} \quad \text{162-Br}$$
$$\text{X = I} \quad \text{162-I}$$

Similarly, a variety of dimethylethylene, trimethylethylene, and tetramethylethylene halonium ions have been prepared and studied by $^1$H and $^{13}$C NMR spectroscopy.$^{99,386,389}$ Some of the representative examples are ions **163–166**.

$$\text{H}_3\text{C} \begin{array}{c} \text{X} \\ \text{H}_3\text{C} \end{array} \quad \text{H}_3\text{C} \begin{array}{c} \text{X} \\ \text{H}_3\text{C} \end{array} \quad \text{H}_3\text{C} \begin{array}{c} \text{X} \\ \text{H}_3\text{C} \end{array} \quad \text{H}_3\text{C} \begin{array}{c} \text{X} \\ \text{H}_3\text{C} \end{array}$$

$$\text{X = Cl, Br} \quad \text{X = Br, I} \quad \text{X = Cl, Br, I} \quad \text{X = Cl, Br, I}$$

**163**  **164**  **165**  **166**

The unsymmetrical halonium ions such as **165-Br** are found in equilibrium with open-chain $\beta$-bromocarbenium ion. Many of the above-mentioned halonium ions have been prepared by the protonation of the appropriate cyclopropyl halides in superacids.$^{390}$

Attempts to obtain the tetramethylfluoronium ion **166-F** has, however, been unsuccessful.$^{340}$ Ionization of 2,3-difluoro-2,3-dimethylbutane in SbF$_5$–SO$_2$ at $-60^\circ$C gave an equilibrating $\beta$-fluorocarbenium ion **167**. The equilibration was shown to occur through the intermediacy of 1-tert-butyl-1-fluoroethyl cation **168** by a recent $^{13}$C NMR spectroscopic study.$^{391}$

$$\text{CH}_3 \begin{array}{c} \text{X} \\ \text{CH}_3 \end{array} \quad \text{CH}_3 \begin{array}{c} \text{F} \\ \text{CH}_3 \end{array} \quad \text{CH}_3 \begin{array}{c} \text{F} \\ \text{CH}_3 \end{array} \quad \text{CH}_3 \begin{array}{c} \text{F} \\ \text{CH}_3 \end{array}$$

**167**  **168**

Strating, Wieringa, and Wynberg$^{392,393}$ reported that adamantylideneadamantane, a highly sterically hindered olefin, reacted with chlorine in hexane and bromine in CCl$_4$ solution to give the corresponding chloronium and bromonium salts **169**. They proposed the structure of these rather insoluble salts (on which no spectroscopic study was conducted) to be that of three-membered-ring ethylenehalonium ions ($\sigma$-complexes). Olah et al.$^{388}$ subsequently investigated these stable salts by $^1$H and
13C NMR spectroscopy, and concluded that they are not three-membered-ring halonium ions but molecularly bound π-complexes 170.

Nugent\textsuperscript{394} has isolated the hexafluoroantimonate salt of 169-Cl and subsequently Brown and co-workers\textsuperscript{395,396} established the molecular structure of the Br\textsubscript{3}− and triflate salts of 169-Br and the triflate of 169-I by X-ray crystal structure analysis. The halonium portion of the triflate salts were found to be essentially symmetric (averaged structural parameters for 169-Br: Br–C bond length = 2.11 Å, C–C bond length 1.49 Å, Br–C–C angle = 69.4°, C–Br–C angle = 41.3°). It was also observed that addition of the parent olefin results in translocation of Br\textsuperscript+ from the top side of the halonium ion to its bottom side in an equilibrium process. Kochi and co-workers\textsuperscript{397} obtained the hexachloroantimonate salt of 169-Cl and showed to have an unsymmetrical cyclopropane ring system. Chlorine is ascribed to be σ-bonded to a single carbon center, and the cationic charge on the adjacent carbon is stabilized by the chlorine lone pair acting as π-donor. The 1-methyl- and 4-chloro-substituted derivatives of 169-Br have also been characterized by 1H and 13C NMR spectroscopy.\textsuperscript{398,399}

**Trimethylenehalonium Ions.** Attempts to prepare trimethylenehalonium ions by ionizing the appropriate 1,3-dihaloalkanes with SbF\textsubscript{5}–SO\textsubscript{2} or with 1:1 HSO\textsubscript{3}F–SbF\textsubscript{5}–SO\textsubscript{2} solution at low temperature have been unsuccessful.\textsuperscript{400} The ions obtained were either three- or five-membered-ring halonium ions, formed through ring contraction or ring expansion, respectively. For example, when 1-halo-3-iodopropanes were reacted with SbF\textsubscript{5}–SO\textsubscript{2}ClF solution at −78°C, the propyleneiodonium ion 162-I is formed (Scheme 4.12). This ion could be formed through the trimethyleneliodonionium ion 171,

\[
\begin{align*}
\text{ICH}_2\text{CH}_2\text{CH}_2X & \quad \text{SbF}_5\text{–SO}_2\text{ClF} \\
\text{X} &= \text{Cl, I} \\
\text{171} & \quad \text{HC}^+\text{C}—\text{CH}_2 \\
\text{162-I} & \quad \text{H}_3\text{C}\quad \text{CH}_2^+ \\
\end{align*}
\]
which was, however, not observed as an intermediate. Alternatively, the nonassisted primary ion could undergo rapid 1,2-hydrogen shift to the secondary ion, which then would form the propyleneiodonium ion via iodine participation. 1-Halo-3-bromopropanes behave similarly yielding 162-Br.

The ionization of 1,3-dihalo-2-methylpropanes with SbF$_5$–SO$_2$ClF gave both three-membered and five-membered ring halonium ions and open-chain halocarbenium ions.

The only reported preparation of long-lived four-membered-ring halonium ions is that reported by Exner et al.$^{401}$ 3,3-Bis(halomethyl)trimethylenebromonium ions 172 were prepared by treating tetrahaloneopentanes with SbF$_5$–SO$_2$ClF solution at low temperature [Eq. (4.117)]. Seemingly, halogen substitution stabilizes the four-membered ring. The $^1$H NMR spectrum of fluorinated ion 172-F shows a broad singlet at $\delta^1$H 5.28 and a doublet at $\delta^1$H 4.68 ($J_{H-F} = 47$ Hz). In contrast, the brominated ion 172-Br displays a temperature-dependent proton absorption at $\delta^1$H 5.17 (from internal Me$_4$N$^+$BF$_4^-$), indicating the occurrence of the exchange process shown.

\[
\begin{align*}
X'CH_2C(CH_2X)CH_2Br & \xrightarrow{\text{SbF}_5-\text{SO}_2\text{ClF}} \text{BrCH}_2CH_2Br \\
X = X' = F & \quad \text{XCH}_2CH_2Br \\
X = X' = Br & \quad \text{BrCH}_2CH_2Br \\
X = Br, X' = F & \quad \text{H}_2CCH_2Br
\end{align*}
\]

\(172\) \(172\-F\) \(172\-Br\)

\(\text{Tetramethylenehalonium Ions.}\) 1,4-Halogen participation was first postulated to occur in the acetylation of 4-iodo- and 4-bromo-1-butyl tosylates.$^{402}$ In subsequent studies, Peterson and coworkers found anomalous rates in the addition of trifluoroacetic acid to 5-halo-1-hexenes$^{403,404}$ and 5-halo-1-pentynes.$^{405,406}$ Such observations were recognized as due to 1,4-halogen participation.$^{341}$ Also, a study of the solvolysis of $\delta$-chloroalkyl tosylates indicated rate-accelerating 1,4-chlorine participation effects up to 99-fold.$^{407}$

Direct experimental evidence for 1,4-halogen participation comes from the direct observation (by NMR spectroscopy) of five-membered-ring tetramethylenehalonium ions by Olah and Peterson$^{408}$ and by Olah et al.$^{400}$

The ionization of 1,4-dihalobutanes in SbF$_5$–SO$_2$ solution gave the parent tetramethylenehalonium ions 173 [Eq. (4.118)].$^{408,409}$ The $^1$H NMR spectra of these ions are similar to each other. Subsequently it was found that even 1,2- and
1,3-dihalobutanes when reacted with SbF$_5$–SO$_2$ solution$^{400}$ give the same tetramethylenehalonium ions$^{365}$ [Eq. (4.119)].

\[
\begin{align*}
XCH_2CH_2CH_2CH_2X & \quad \xrightleftharpoons[\text{SbF}_5\cdots\text{SO}_2; -60^\circ\text{C}]{\text{XCH}_2\text{CHXCH}_2\text{CH}_3} \quad \text{X} = \text{Cl, Br, I} \\
XCH_2CHXCH_2CH_3 & \quad \xrightleftharpoons[\text{SbF}_5\cdots\text{SO}_2; -40^\circ\text{C}]{\text{XCH}_2\text{CH}_2\text{CHXCH}_2X} \quad \text{X} = \text{Cl, Br} \\
XCH_2CH_2CH_2CH_2I & \quad \xrightleftharpoons[\text{SbF}_5\cdots\text{SO}_2; -40^\circ\text{C}]{\text{XCH}_2\text{CHCH}_2\text{CH}_2\text{CH}_2I} \quad \text{X} = \text{Cl, Br, I}
\end{align*}
\]

Similarly, several 2- and 2,5-substituted tetramethylenehalonium ions (174–178) have been prepared and studied by both $^1$H and $^{13}$C NMR spectroscopy.$^{99,410,411}$

\[
\begin{align*}
174 & \quad \xrightleftharpoons{\text{CH}_3} \quad X = \text{Cl, Br, I} \\
175 & \quad \xrightleftharpoons{\text{CH}_3} \quad X = \text{Br} \\
176 & \quad \xrightleftharpoons{\text{CH}_3} \quad X = \text{Cl, Br} \\
177 & \quad \xrightleftharpoons{\text{CH}_3} \\
178 & \quad X = \text{Cl} \\
179 & \quad X = \text{Br}
\end{align*}
\]

The 2,2,5,5-tetramethyltetramethylenechloronium ion 178-Cl shows only one $^1$H and $^{13}$C NMR signal for the nonequivalent methyl groups indicating that some kind of equilibrium exists with the open-chain carbenium ion.$^{411}$

Even 2-methylenetetramethyleneliodoniuim ion 179 has been prepared by the protonation of 5-iodopentyn$^{405,406}$ [Eq. (4.120)].

\[
\begin{align*}
\text{HC} \equiv \text{CCH}_2\text{CH}_2\text{CH}_2\text{I} & \quad \xrightleftharpoons[\text{HSO}_3\text{F}_5\cdots\text{SbF}_5\cdots\text{SO}_2; -78^\circ\text{C}]{\text{HC} \equiv \text{CCH}_2\text{CH}_2\text{CH}_2\text{I}} \\
179 & \quad \xrightleftharpoons{\text{H}} \\
\end{align*}
\]

**Pentamethylenehalonium Ions** Attempts to prepare six-membered-ring halonium ions by treating 1,5-dihalopentanes with SbF$_5$–SO$_2$ gave exclusive rearrangement to five-membered-ring halonium ions.$^{99,408}$ Peterson et al.$^{412}$, however, were able to prepare six-membered-ring halonium ions 180 by the methylation of 1,5-dihalopentanes with methyl fluoroantimonate (CH$_3$F–SbF$_5$) in SO$_2$ solution$^{412}$.
However, some rearrangement to five-membered-ring halonium ions was also observed.

$$\text{XCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{X} \xrightarrow{\text{CH}_3\text{F-SbF}_5\text{-SO}_2} \xrightarrow{\text{X} = \text{Br}} \text{55–72%} \quad \xrightarrow{\text{X} = \text{I}} \text{95%}$$

(4.121)

Alternatively, six-membered-ring halonium ions were also formed when equimolar amount of 1,5-dihalopentane was added to dihalonium ions [Eq. (4.122)]. The dihalonium ions were prepared from 1,5-dihalopentane and 2 mol of methyl fluorooantimonate. Furthermore, the dimethylbromonium ion is also a sufficiently active methylating agent to form cyclic pentamethylenebromonium ion from 1,5-dibromopentane [Eq. (4.123)].

$$\text{X(CH}_2)_5\text{X} \xrightarrow{2\text{CH}_3\text{F-SbF}_5\text{-SO}_2} \text{CH}_3\text{X(CH}_2)_5\text{XCH}_3\text{(SbF}_6\text{)}^2 \xrightarrow{\text{X(CH}_2)_5\text{X}} 2\xrightarrow{\text{X} = \text{Br}} \text{80-Br}$$

(4.122)

(4.123)

**Bicyclic Halonium Ions.** Although halogen addition to cycloalkenes are assumed to proceed through the corresponding bicyclic halonium ions, these ions are quite elusive. Olah, Liang, and Staral were able to prepare the cyclopentenebromonium ion by the ionization of trans-1,2-dibromocyclopentane in SbF$_5$–SO$_2$ClF solution at $-120^\circ$C [Eq. (4.124)]. The $^1$H NMR (60 MHz) spectrum of the ion solution showed a broadened peak at $\delta^1$H 7.32 (two protons) and two broad peaks centered at $\delta^1$H 3.14 (four protons), and $\delta^1$H 2.50 (two protons). The $^1$H NMR spectrum of the solution also showed the presence of the related cyclopentenyl cation. When the solution was slowly warmed up to $-80^\circ$C, the cyclopentenebromonium ion gradually and cleanly transformed into the allylic ion. The cyclopentenyl ion present initially in solution might be formed as a result of local overheating during preparation.

$$\text{Br(CH}_2)_5\text{Br} + \text{CH}_3\text{BrCH}_3\text{SbF}_6^- \xrightarrow{-2\text{CH}_3\text{Br}} \text{180-Br} \quad \text{73%} \quad \text{180-Br} \quad \text{174-Br} \quad \text{27%}$$

(4.123)
The cyclopentenebromonium ion 181 was also obtained via protonation of 4-bromocyclopentene in HSO$_3$F–SbF$_5$–SO$_2$ClF solution at −120°C, through the reaction sequence shown in Eq. (4.125). The proton noise-decoupled $^{13}$C NMR spectrum of the cyclopentenebromonium ion 181 shows three carbon resonances at δ$^{13}$C 114.6 (doublet, $J_{C-H} = 190.6$ Hz), 31.8 (triplet, $J_{C-H} = 137.6$ Hz), and 18.7 (triplet, $J_{C-H} = 134.0$ Hz).

Attempts were also made to prepare the cyclopentenechloronium ion 182 via ionization of trans-1,2-dichlorocyclopentane in SbF$_5$–SO$_2$ClF solution at −120°C. However, instead of the cyclopentenechloronium ion 182 only the 1-chloro-1-cyclopentyl cation 183 was obtained [Eq. (4.126)]. Apparently, the participation of the smaller chlorine atom could not effectively compete with the fast 1,2-hydride shift forming the tertiary ion. The larger bromine atom, however, preferentially participates with the neighboring electron-deficient center, forming the bicyclic bridged ion.

Olah, Prakash, and co-workers$^{414}$ have isolated an unusual fluorinated product in the transformation of bromocyclohexane and suggested the involvement of 7-bromoniabicyclo[4.1.0]heptane 184 [Eq. (4.127)].

The attempted generation of ion 184 in a subsequent study$^{415}$ resulted in the exclusive formation of 7-bromoniabicyclo[2.2.0]heptane 185 (Scheme 4.13) identified unequivocally on the basis of its NMR characteristics [δ$^{13}$C 118.7 ($J_{C-H} = 172.1$ Hz) and 37.4 ($J_{C-H} = 135.5$ Hz)]. Calculations have shown (MP2/BB2/MP2/SB level)$^{416}$
that on the potential energy surface of the C\textsubscript{6}H\textsubscript{10}X\textsuperscript{+} cations (X = F, Cl, Br), the 1,4-bridged bromonium ion 185 is the most stable species being more stable than the 1-bromocyclohexylum cation and the 1,2-bridged ion by about 5 kcal mol\textsuperscript{-1} and 10 kcal mol\textsuperscript{-1}, respectively. The corresponding chloro derivatives are of equal energy, whereas the 1-fluorocyclohexylum cation is considerably more stable than the 1,4-fluoro-bridged ion. On the basis of these results, the unsuccessful attempt to prepare the 1,2-bridged ion 184 is not surprising. Similar studies of the bromocyclopentyl cations found the 1,2-bridged ion more stable than its isomers. Electrostatic and size effects seem to dominate the stability of these cations.

Peterson and Bonazza\textsuperscript{417} have reported that ionization of \textit{cis}-1,2-bis(chloromethyl) cyclohexane in SbF\textsubscript{5}–SO\textsubscript{2} solution at \textdegree C \textsubscript{78} gives the bicyclic five-member-rig chloronium ion 186 along with smaller amounts of other species [Eq. (4.128)]. Warming the solution containing the ion to \textdegree C \textsubscript{10} leads to the formation of the open-chain tertiary carbenium ion 187.

Hall, Gabbai, and co-workers\textsuperscript{418} have obtained the tetrafluoroborate salt of cation 188 from the 1,8-bis(diphenylmethylium)naphthalenediyldication [Eq. (4.129)]. The molecular structure shows that the C(1) atom is tetrahedral, C(2) has a trigonal planar arrangement, and the C–F bond is a regular bond (1.424 Å). The fluorine forms a long interaction with the methylium center (2.444 Å) and the C(1)–F–C(2) angle is 111.11° characteristic of a formally \textit{sp}\textsuperscript{3}-hybridized F atom. DFT calculations, AIM analysis, and Boys localized orbitals indicate that the long C(2)–F interaction is a dative bond and the unsymmetrical 188\textsubscript{b} structure must also contribute. Indeed, variable-temperature \textsuperscript{1}H NMR measurements show that 188 is a fluxional ion and the fluorine
atom oscillates between the two carbon centers involving a symmetrical fluoronium ion as low-energy transition state.

\[
\text{Me}_3\text{SiF}_2^- \cdot (\text{Me}_2\text{N})_3\text{S}^+ \rightarrow \text{MeCN, } -78^\circ\text{C} \rightarrow \]

\[\text{a} \quad \text{b} \quad 188\]

**Heteroaromatic Halophenium Ions.** Halophenium ions are a class of halonium ions analogous to thiophene, furan, and pyrrole. To date, no parent halophenium ions are known, but many stabilized tetraphenyl iodophenium, benzoiodophenium, and dibenzoiodophenium ions have been prepared by Beringer and co-workers.\(^{419,420}\) Some of them have been analyzed by X-ray crystal structure investigations. Representative examples are ions 190–192.

\[
\begin{align*}
\text{189} & \quad \text{190} & \quad \text{191} & \quad \text{192} \\
\end{align*}
\]

Olah and Yamada\(^{421}\) have shown that thermal decomposition of \textit{ortho-}(\beta,\beta\text{-dichloroethenyl})phenyl diazoniumfluorophosphate yielding \textit{ortho-}(\beta\text{-chloroethynyl}) chlorobenzene involves benzochloronium ion 193 as the intermediate [Eq. (4.130)].

\[
\begin{align*}
\text{193} \\
\end{align*}
\]

**Miscellaneous Halonium Ions.** The Si-containing ring system 194 analogous to 188 has been reported by Müller and co-workers.\(^{422}\) The silyl cation is stabilized by intramolecular interactions with the F atoms increasing the coordination number of Si and, consequently, Si becomes considerably shielded. In the \(\delta\text{Si}^{29}\) NMR spectrum, the resonance at \(\delta\text{Si}^{29} 77\) indicate that cation 194 has only a small silicenium ion character.
and better be described as a fluoronium ion. Characteristic data for cation 194 are as follows: Si–F bond lengths = 1.755 and 1.763 Å, Si–F–Si angle = 129.9°. This is in sharp contrast to the structure of ion 188. Cations 195 have similar characteristics (δ²⁹Si 90.2–90.8). X-ray crystal analysis shows that the Si–X–Si bridge in these cations is symmetric.

Y = F, Cl, Br

4.2.5. Onium Ions of Group 15 Elements

4.2.5.1. 2-Azoniaallene and Derived Cations. Various monocations can be derived from allenes by replacing the carbons by nitrogen atoms. Whereas only a few examples of ketiminium salts 196 are known, 2-azoniaallene salts (197) can be prepared by a number of methods. They are well-characterized and used widely in dipolar cycloadditions. Spectroscopic studies of hexachloroantimonate salts of phenyl-substituted cations 197 first synthesized by Würthwein and X-ray crystallographic analysis of various salts including 198 indicate a C = N = C unit, that is, the allene geometry (197a, D₂ᵥ symmetry). Experimental and theoretical studies reveal, however, that depending on the substitution pattern and particularly with amino and alkoxy substituents, the ions may exist as bent 2-azaallyl cations 197b (C₂ᵥ symmetry) or adopt structures in between.
Cation 199 synthesized according to Eq. (4.131) has, for example, a chiral, bent geometry with the ethoxy substituents in \textit{exo} position in \textit{s-cis} conformation (C–N–C angle = 133.0°, torsional angle = 70.4°). The 2-azaallyl structure 200 of the parent tetrahydroxy model compound (\(C_2\) symmetry) was shown by quantum mechanical calculations to be 20 kcal mol\(^{-1}\) lower in energy than the corresponding 2-azoniaallene.

\[
\begin{align*}
\text{R}^1 & = \text{Me, Et} \\
\text{R}^2, \text{R}^3 & = \text{Me, Et, isoPr, tert-Bu, Ph, 4-MeC}_6\text{H}_4 \\
\text{Y} & = \text{BF}_4^-, \text{SbCl}_6^-
\end{align*}
\]

A variety of 1-aza-2-azoniaallene salts 201 have been developed and are in use as reactive intermediates in cycloadditions. According to X-ray analysis, methylation of \textit{di-}tert-butylcarbodiimide yielded cyanamidium salt 202a (N–C bond lengths 1.15 and 1.25 Å, C–N–C bond angle = 177°) instead of the expected carbodiimidium salt 202b.

\[
\begin{align*}
\text{R, R}' & = \text{tert-Bu, aryl, COOR} \\
\text{R}^1, \text{R}^2 & = \text{alkyl, aryl, Cl} \\
\text{Y} & = \text{AlCl}_4^-, \text{SbCl}_6^-
\end{align*}
\]

Jochims and co-workers synthesized 1-oxa-3-azabutatrienium and 1-thia-3-azabutatrienium chloroantimonates [Eq. (4.132)]. X-ray structure analysis of the phenyl-4-bromophenyl-substituted derivatives shows bent structures (C = N = C angles for X = O and S, respectively, are 129° and 139°). Bond distances indicate that all possible mesomeric structures contribute to the structure of the O analog. In contrast, the mesomeric form with a C=S\(^+\) moiety appears to be less important. \(^{13}\)C NMR data suggest a certain delocalization of the positive charge into the aromatic rings.

\[
\begin{align*}
\text{R, R}' & = \text{tert-Bu, Ph, 4-BrC}_6\text{H}_4, \\
\text{X} & = \text{O, S}
\end{align*}
\]
Seppelt and co-workers\textsuperscript{439} isolated various salts of the cation OCNCO\textsuperscript{+} [Eq. 4.133]]. The molecular structure of OCNCO\textsuperscript{+}Sb\textsubscript{3}F\textsubscript{16}\textsuperscript{−} comprises a strongly bent cation (N–C–O angles = 173.1 and 173.6°, C–N–C angle = 130.7°). This finding is in good agreement with the structure of the ion calculated by Pyykkö and Runeberg\textsuperscript{440} using \textit{ab initio} methods (C–N–C angle = 138.6 and 139.4°). It is to be noted that the N\textsubscript{5}\textsuperscript{+} cation (217, vide supra) is also strongly bent at the central nitrogen atom.

\[
\begin{align*}
\text{F} & \text{−CO−NCO + MF} & \text{O} & \text{CNCO}^+ \text{X}^- \\
\text{M} = \text{Sb, As} & \text{CF}_3\text{CH}_2\text{CF}_3 \text{or CF}_2\text{Cl}_2 & \text{−196°C to RT} & \text{X} = \text{Sb}_3\text{F}_{16}, \text{AsF}_6, \text{As}_2\text{F}_{11}
\end{align*}
\]

(4.133)

4.2.5.2. Diazonium Ions

\textit{Parent Diazonium Ion.} The simplest diazonium ion, protonated dinitrogen 203, is still elusive. In fact, molecular nitrogen is a very weak base. \textit{Ab initio} calculations of protonated dinitrogen have shown\textsuperscript{441} that the end-protonated linear structure 203 of C\textsubscript{2}v symmetry is energetically preferred over the edge-protonated cyclic ion 204 of C\textsubscript{v} symmetry. Subsequent high-level calculations [HF/6-31G** and MP2(FU)/6-31G** levels] by Rasul, Prakash, and Olah\textsuperscript{442} have found that the cyclic structure is a transition state for N\textsubscript{a}–N\textsubscript{b} rearrangement with an energy barrier of 47.1 kcal mol\textsuperscript{−1}. The N–N bond distance in 203 is slightly shorter than that in dinitrogen (1.124 Å versus 1.130 Å). Further protonation leads to linear diprotonated dinitrogen (protodiazonium dication), which is less stable by 60.5 kcal mol\textsuperscript{−1} than ion 203 but dissociation to 203 and H\textsuperscript{+} has a kinetic barrier of 28.7 kcal mol\textsuperscript{−1}.

\begin{align*}
\text{HN} & \text{N}_2 \rightarrow \text{HN}^+ \overset{+}{\text{N}}_2 \text{N} \\
\text{203} & \text{204}
\end{align*}

Using an indirect approach, Olah et al.\textsuperscript{443} were able to diazotize ammonia [Eq. (4.134)], bis(trimethylsilyl)amine, and isocyanic acid with \textsuperscript{15}NO\textsuperscript{+}BF\textsubscript{4}−, resulting in the formation of \textsuperscript{14}N\textsuperscript{15}N, which requires the intermediacy of the parent diazonium ion HN\textsubscript{2}\textsuperscript{+}.

\[
\begin{align*}
\text{14NH}_3 & + \text{15NO}^+\text{BF}_4^- \xrightarrow{\text{CH}_2\text{Cl}_2, -80°C} [\text{15N} \equiv \text{14NH}]^+\text{BF}_4^- \\
& \xrightarrow{-\text{H}_2\text{O}} 15\text{N} \equiv 14\text{N} + \text{HBF}_4
\end{align*}
\]

(4.134)

Protonated (deuterated) nitrogen has been studied in the gas phase,\textsuperscript{444,445} but attempts to observe it in the condensed phase were unsuccessful.\textsuperscript{443} An analog of 203, fluorodiazonium ion 205, is, however, known. Ionization of \textit{cis}-difluorodiazine
with arsenic pentafluoride below ambient temperature gives fluorodiazonium hexa-
fluoroarsenate 205 as a white solid.\textsuperscript{446} The same reaction does not occur with trans-
difluorodiazine. The salts of ion 205 have been studied by X-ray diffraction, vibrational spectroscopy, and NMR spectroscopy.\textsuperscript{447–449} Both nitrogens are more shielded compared with benzenediazonium ion, and \( N_\beta \) is deshielded relative to \( N_\alpha \) (\( \delta^{14}\text{N} = -166.1 \) versus \( -191.2 \) relative to \( \text{CD}_3\text{NO}_2 \)).\textsuperscript{448} The \( J_{\text{14N–F}} \) value measured for 205 at 339.0 Hz is the largest known \( ^{19}\text{F–}^{14}\text{N} \) coupling constant, indicating the high \( \sigma \)-character of the nitrogen–nitrogen bond.\textsuperscript{448} In a subsequent study of the hexa-
fluoroarsenate salt of ion 205 the \( \text{F–N} \) and \( \text{N=N} \) bond lengths were determined (1.217 and 1.099 Å, respectively).\textsuperscript{449} The \( \text{F–N} \) bond distance is the shortest \( \text{F–N} \) bond length known, whereas the \( \text{N=N} \) bond length is close to the value measured for \( \text{N}_2 \) (1.0976 Å). The shortness of both bonds is interpreted as resulting from the high \( \sigma \)-character of the \( \text{N} \) molecular orbital and the formal positive charge on the cation.

\[
\text{F} - \overset{\alpha}{\text{N}} - \overset{\beta}{\equiv \text{N}} - \overset{\text{M}}{\text{F}_6^–}
\]

\( \text{M} = \text{As, Sb} \)

**Alkylidiazonium Ions.** The intermediacy of alkylidiazonium ions in a variety of organic reactions is well established.\textsuperscript{450–452} They are common intermediates in the acid-catalyzed decomposition of diazo compounds and the nitrous acid-induced deamination of aliphatic primary amines. The evidence for \( \text{RN}_2^+ \) (\( R = \text{alkyl} \)) intermediates come from both rate data and product analysis studies. However, direct investigation of alkylidiazonium ions has been difficult due to their instability.

The first direct observation\textsuperscript{453} of an aliphatic diazonium ion was achieved by protonation of trifluoromethyldiazomethane in \( \text{HSO}_3\text{F} \) at \(-60^\circ\text{C} \). The 2,2,2-
trifluoroethylidiazonium ion 206 is stable for 1 h at \(-60^\circ\text{C} \). Similarly bis(trifluor-
omethyl)methane diazonium ion 207 has been prepared and characterized.\textsuperscript{454} These ions were studied by \( ^1\text{H} \) NMR spectroscopy. Similar diazonium structures have been assigned to protonated 2-diazo-5\( \alpha \)-cholestan-3-one.\textsuperscript{455} None of these studies, however, showed nitrogen protonation.

\[
\begin{align*}
\text{CF}_3\text{CH}_2\text{N}_2^+ & \quad \text{CF}_3 \\
\text{CH} - \text{N}_2^+ & \quad \text{CF}_3
\end{align*}
\]

Subsequently, McGarrity and Cox\textsuperscript{456} have succeeded in protonating diazomethane in \( \text{HSO}_3\text{F} – \text{SbF}_5 – \text{SO}_2\text{ClF} \) at \(-120^\circ\text{C} \). In this acid media, exclusive formation of methylidiazonium ion \( \text{CH}_3\text{N}_2^+ \) 208, the thermodynamically more stable product, is observed. With a more acidic \( \text{HSO}_3\text{F} – \text{SbF}_5 \) system, both methylidiazonium ion 208 and methylenediazenium ion 209 are observed in a ratio corresponding to their
gas-phase stabilities. The two ions 208 and 209 have been characterized by $^1$H, $^{13}$C, and $^{15}$N NMR spectroscopy.

Early *ab initio* calculations predicted$^{457,458}$ that the open structure 208a is significantly more stable than the bridged cation 208b. High-level studies$^{442}$ [MP2 (FU)/6-31G**] have recently found that C-protonated diazomethane (208a) is more stable than the $N$-protonated CH$_3$N$_2$H$^+$ isomer (209) by 39.3 kcal mol$^{-1}$. Glaser and co-workers$^{459,460}$ studied the methyldiazenium cation and ethyldiazenium cation and found a remarkable difference of 30.7 kcal mol$^{-1}$ for the dediazoniation enthalpy for the ions (42.2 versus 11.5 kcal mol$^{-1}$). A small part (5.6 kcal mol$^{-1}$) of the difference may be accounted for by the formation of the nonclassical ethyl cation. It was also concluded that alkyldiazenium ions are best described as carbocations and Lewis structures do not adequately describe the structure of these ions. Of the diprotonated diazomethanes,$^{442}$ the $N$,$N$-diprotonated structure was found to be the global minimum, which is more stable than the $C$,$N$-diprotonated and $C$,$C$-diprotonated forms by 11.3 kcal mol$^{-1}$ and 34.3 kcal mol$^{-1}$, respectively.

The stability of alkyldiazenium ions may be greatly increased by an appropriate molecular structure. Bott has reported the generation of a variety of stable vinyldiazenium ions$^{461}$ [Eqs. (4.135) and (4.136)]. The results are summarized in reviews.$^{462,463}$

Glaser and co-workers$^{464,465}$ determined the X-ray crystal structure of $\beta$,$\beta$-disubstituted ions 210 and 211. Structural parameters indicate that carbenium ion
resonance forms stabilized by heteroatoms (O and Cl), particularly the type 210b, contribute most to the overall stability of the ions.

Levisalles and co-workers466 and Wentrup and Dahn467 studied enoldiazonium ions generated under superacidic conditions. More recently Laali and coworkers468 have shown that the stability of enoldiazonium ions can be greatly enhanced by an α-silyl functionality. Equation (4.137) shows the characteristic diazonium ion products.

\[(4.137)\]

**Aromatic Diazonium Ions.** In contrast to alkyl diazonium ions, aryldiazonium ions are well-studied.469–477 They were known as early as 1894. They are isolable as ionic salts with a variety of counterions such as BF\(_4^-\), PF\(_6^-\), SbCl\(_6^-\), SbF\(_6^-\), AsF\(_6^-\), and ClO\(_4^-\). They undergo a variety of nucleophilic reactions and an excellent review is available on the subject.478

The ambident reactivity of aryldiazonium ions has also been established.479 The diazonium group is an interesting substituent on the aryl ring and by far the most strongly electron-withdrawing substituent known (\(\sigma_p = 1.8\)).480 A 13C NMR spectroscopic investigation on a series of aryldiazonium ions481 seems to support the above fact and also indicates their ambident electrophilic character.478 Aryldiazonium ions undergo interesting reaction of N\(_a\)–N\(_b\) inversion catalyzed by metals that complex molecular nitrogen (Scheme 4.14), probably through the intermediacy of a phenyl cation.482–488 Such inversions have been observed by Zollinger and co-workers489,490 in dediazonation reaction of β-\(^{15}\)N-labeled diazonium ions with nitrogen gas under pressure (300 atmosphere) (Scheme 4.14). Such exchange reactions have been further studied with sterically hindered 2,6-disubstituted diazonium ions.491,492

The study of 2,6-disubstituted benzenediazonium ions492 did not show the presence of any persistent C-protonated benzenediazonium dication even in Magic Acid [Eq. (4.138)], reinforcing the notion that charge delocalization into the aromatic ring plays a significant role.
In contrast, Laali and Olah\textsuperscript{493} were able to $O$-protonate para-methoxybenzene-diazonium ion in HSO$_3$F–SbF$_5$–SO$_2$ClF solution [Eq. (4.139)]. The C(4) carbon in the dication is slightly shielded relative to the precursor whereas all other carbons are deshielded. Unlike the para-methoxybenzenediazonium ion, the ortho-methoxybenzenediazonium ion is not $O$-protonated under similar conditions due to the proximity of the developing positive charge of the oxonium ion with the N$_2^+$\textsuperscript{4}. Attempted $O$-methylation with MeF–SbF$_5$–SO$_2$ was unsuccessful.

\begin{equation}
\begin{array}{c}
\text{Ar}^+\text{N}^\equiv\text{N}^{\text{15N}} \rightleftharpoons \text{Ar}^+\text{N}^\equiv\text{N} \\
\text{Ar} - ^\equiv\text{N}_2^+ + \text{N}_2 \rightleftharpoons \text{Ar} - ^\equiv\text{N}_2^+ + ^\equiv\text{N}_2
\end{array}
\end{equation}

Scheme 4.14

Diazonium dications bearing two aryl rings have been observed by treating azoxybenzenes in HF–SbF$_5$ [Eq. (4.140)]. The ortho and para protons are deshielded relative to the meta protons, which is indicative of charge delocalization into the aromatic rings.

\begin{equation}
\begin{array}{c}
\text{R} - \text{N} = \text{N} - \text{O} \rightleftharpoons \text{R} - \text{N} = \text{N} - \text{O} \\
\text{R} = \text{H, Cl}
\end{array}
\end{equation}

Other Substituted Diazonium Ions. A series of aminodiazonium ions have been prepared under superacidic conditions [Eq. (4.141)]. Schmidt\textsuperscript{495} described the preparation and IR spectra of protonated hydrazoic acid \textbf{212} and methylazide as their hexachloroantimonate salts. Olah and co-workers\textsuperscript{496} have carried out a comprehensive study on aminodiazonium ions (protonated azides) by $^1$H, $^{13}$C, and $^{15}$N NMR spectroscopy. Even the electrophilic aminating ability of aromatics of \textbf{212} has been explored.\textsuperscript{496} The tetrachloroaluminate salt of \textbf{212} has also been prepared\textsuperscript{496}
[Eq. (4.142)] and the tetrafluoroborate was also generated by reacting Me₃SiN₃ with HF–BF₃–SO₂ClF.⁴⁹⁶

\[
\text{HN}_3 + \text{HSO}_3\text{F–SbF}_5 \quad \text{or} \quad \text{HF–SbF}_5 \quad \text{or} \quad \text{HF–BF}_3 \quad \rightarrow \quad \text{H}_2\text{N} \rightleftharpoons \text{N} \quad \overset{+}{\text{Y}}^{-} \quad \text{(4.141)}
\]

\[
\text{Y} = \text{BF}_4, \text{SbF}_6
\]

\[
\text{NaN}_3 + \text{AlCl}_3 + 2 \text{HCl} \quad \rightarrow \quad \text{H}_2\text{N} \rightleftharpoons \text{N} \quad \overset{+}{\text{AlCl}_4}^{-} + \text{NaCl} \quad \text{(4.142)}
\]

The evidence for the aminodiazonium structure 212 for the protonated hydrazoic acid comes from \(^{15}\)N NMR spectroscopy and molecular structure of the hexafluoroantimonate salt.⁴⁹⁷ These studies showed that both hydrogens are bonded to the same nitrogen, which has a pyramidal structure (212). The N–N single and triple bond lengths are quite different (1.295 versus 1.101 Å) and the N–N–N bond is slightly distorted (bond angle = 175.3°). Gas-phase protonation of hydrazoic acid has been studied by Cacace et al.⁴⁹⁸,⁴⁹⁹ Gas-phase proton affinity was found experimentally to be 180 ± 2 kcal mol⁻¹, whereas the calculated value is 179.4 ± 1 kcal mol⁻¹. The iminodiazenium (1,3-diaza-2-azoniaallene) structure 213 is not observed in the case of either hydrazoic acid or the alkyl azides. Various salts (AlCl₄⁻, SbCl₆⁻, PF₆⁻) of substituted 1,3-diaza-2-azoniaallene cations have recently been synthesized.⁵⁰⁰,⁵⁰¹ The strong absorption at 2012 cm⁻¹ was assigned to the symmetric stretching vibration of the N = N⁺ = N unit, which was shown by AM1 calculations to have a bent structure (155°).

Alkyl azides are also protonated to alkylaminodiazonium ions 214 (Scheme 4.15). Multinuclear NMR studies and calculations for the parent aminodiazonium ion

\[
\begin{align*}
\text{R} & \quad \overset{\text{H}}{\text{N}} & \quad \overset{\text{+}}{\text{N}} & \quad \overset{\text{212}}{\text{R}} = \text{H, Me, Et} \\
\end{align*}
\]

Scheme 4.15
indicate that N(3) has significant positive charge and, therefore, the mesomeric structure \(214b\) is an important contributor to the overall structure.

Rasul, Prakash, and Olah have attempted to generate bisdiazonium dication \(215\) by the diazotization of aminodiazonium ion \(212\) with \(\text{NO}^+\text{BF}_4^-\) (HSO\(_2\text{F}\)–SbF\(_5\)–SO\(_2\)ClF, -78°C), but no further diazotization was observed. The linear \(D_{\text{coh}}\) structure was found to be a minimum on the potential energy surface at various levels of theory. Bond distances represent bisdiazonium character.

\[
\begin{array}{c}
\text{N} & \equiv & \text{N} & + & \text{N} & \equiv & \text{N} \\
1.111 & + & 1.285 & 1.197 & 1.141 & 1.317 & 1.117
\end{array}
\]

The cyanodiazonium ion NCN\(_2^+\) proposed as a transient intermediate in solution, has been observed in the gas phase by Cacace et al. It was generated by ionization of NF\(_3\) and cyanamide and characterized by collisionally activated dissociation. The linear structure of \(C_{\text{en}}\) symmetry (\(216\)) has been found to be the global minimum by high-level \textit{ab initio} calculations [MP2(FU)/6-31G**]. Of the protonated structures the dication protonated on the cyano nitrogen is 55.0 kcal mol\(^{-1}\) more stable.

Christe and co-workers have reported the synthesis [Eq. (4.143)] and full characterization of the homoleptic N\(_5^+\) polynitrogen cation. Both salts are surprisingly stable and decompose at \(-70°C\). Crystal structure of the fluoroantimonate salt \(217\) is in excellent agreement with calculated values (MP2/6-31G* and B3LYP).

\[
\begin{align*}
\text{N}_2\text{F}^+\text{SbF}_6^- + \text{HN}_3 \xrightarrow{\text{HF, } -78 \text{ to } 25^\circ\text{C}} \text{N}_5^+\text{SbF}_6^- \xrightarrow{\text{SbF}_5, 25^\circ\text{C}} \text{N}_5^+\text{Sb}_2\text{F}_{11}^- \\
\end{align*}
\]

Olah et al. have generated long-lived methoxydiazonium ion \(218\) by \(O\)-methylation or transmethylation of N\(_2\)O [Eq. (4.144)]. Multinuclear NMR data indicate that the nature of the N–N bond is quite different from that in benzenediazonium ion. Particularly revealing are the upfield shift of N\(_\beta\) and the N–N coupling (\(\delta^{15}\text{N} 86.8\) versus 316.8, \(J_{\text{N,N}} = 12\) Hz versus <0.7). \textit{Ab initio} calculations (4-31G and 4-31G* levels) show that ion \(218\) is planar and slightly distorted (N–N–O bond angle 173.3°) and has a considerably elongated N–O bond (1.425 Å) compared with that of N\(_2\)O (1.176 Å) and a weak C–O bond (1.489 Å). According to spectroscopic and
computational results, both structures 218b and 218c are significant contributors to the overall structure of the ion.

\[
\begin{align*}
\text{N}_2\text{O} + \text{CH}_3\text{F} & \rightarrow \text{SbF}_5 \quad \text{S} \text{O}_2\text{F}_2 \quad \text{S} \text{O}_2\text{ClF} \\
& \rightarrow \text{N}_2\text{O}_2^+ \\
\text{N}_2\text{O} + \text{CH}_3\text{O}^+ \text{S} \text{O}_2\text{ClF} \text{SbF}_6^- \\
& \rightarrow \text{N}_2\text{O}_2^+ + \text{CH}_3\text{O}^+ \text{SO}_2\text{ClF} \text{SbF}_6^- \\
\end{align*}
\]

(4.144)

Generation of the hydroxydiazonium ion HON$_2^+$ as long-lived species under superacidic conditions was not successful.$^{507}$ According to an early theoretical study, the ion has a structure similar to that of methoxydiazonium ion 218. Recent high-level calculations$^{442}$ [MP2(FU)/6-31G** level] have found the O-protonated structure of $C_3$ symmetry to be the global minimum but it is only 2.5 kcal mol$^{-1}$ more stable than N-protonated nitrous oxide. Of the dications formed by a second protonation, the $O,N$-diprotonated nitrous oxide is more stable than the $O$, $O$-diprotonated nitrous oxide by 7.5 kcal mol$^{-1}$.

Eberlin, Laali, and co-workers$^{508}$ have studied the reaction of N$_2$O with a variety of cations in the gas phase using collision-induced dissociation (CID) for detection and identification of products. Methoxydiazonium ion, MeON$_2^+$, is formed by the reaction of Me$^+$ with N$_2$O. This observation contradicts earlier findings$^{509}$ reporting the preferential formation of the isomeric nitroso-onium ion Me–N$_2$O$^+$. The reaction of PhCH$_2^+$, in turn, does produce the corresponding N-nitroso-onium ion PhCH$_2$–N$_2$O$^+$. 

4.2.5.3. Nitronium Ion (NO$_2^+$). Nitration is one of the most studied and best understood organic reactions.$^{510-512}$ The species responsible for electrophilic aromatic nitration was shown to be the nitronium ion (NO$_2^+$) 219. Since the early 1900s, extensive efforts have been directed toward the identification of this ion, whose existence was first shown by Hantzsch and later firmly established by Ingold and Hughes.$^{510}$

Raman spectroscopic studies in the 1930s on HNO$_3$–H$_2$SO$_4$ mixtures by Médard$^{513}$ showed the presence of nitronium ion 219 in the media. A sharp band at 1400 cm$^{-1}$ was assigned to the symmetric stretching mode of the species. Since then the nitronium ion has been characterized in a variety of Brønsted and Lewis acid mixtures of nitric acid.$^{514}$

There are more than 15 crystalline nitronium salts that have been isolated and characterized with a variety of counterions. The most important salts are of BF$_4^-$,
PF\text{6}^\text{-}, \text{SbF\text{6}^\text{-}}, \text{ClO\text{4}^\text{-}}, \text{FSO\text{3}^\text{-}} \text{counterions. The X-ray crystal structure of nitronium ion is known with hydrosulfate anion.}^{\text{515}} \text{ The most widely used tetrafluoroborate nitronium salt (NO}_2^+\text{BF}_4^-\text{) is prepared by treating a mixture of nitric acid and anhydrous hydrogen fluoride with boron trifluoride}^{\text{516}} [\text{Eq. (4.145)}].

\[
\text{HNO}_3 + \text{HF} + 2\text{BF}_3 \longrightarrow \text{NO}_2^+\text{BF}_4^- + \text{BF}_3\text{-H}_2\text{O} \quad \text{(4.145)}
\]

Nitronium salts are also available from the reaction of NO\text{2}F with SbCl\text{5} followed by anion exchange\textsuperscript{517} [\text{Eq. (4.146)}], and methods have also been developed for the synthesis of the triflate salt.\textsuperscript{517}

\[
\text{NO}_2^+\text{SbCl}_5 \longrightarrow \text{NO}_2^+\text{SbCl}_5\text{F}^- + \text{Me}_4\text{N}^+\text{X}^- \quad \text{(4.146)}
\]

\[
X = \text{ClO}_4, \text{BF}_4
\]

Ingold\textsuperscript{518} was the first to propose that nitric acid anhydride N\text{2}O\text{5} has an ionic structure NO\text{2}^+\text{NO}_3^-\text{. This was later confirmed by Wilson and Christe,}^{\text{519}} \text{who showed a linear symmetric NO}_2^+\text{ with an N–O bond length of about 1.154 Å. The structure of reaction products formed between nitrogen oxides and BF}_3\text{, including NO}_2^+\text{BF}_4^-\text{ was established by Olah and co-workers}^{\text{520, 521}} \text{on the basis of Raman, IR, and X-ray diffraction data.}

In the \textsuperscript{15}N NMR spectrum,\textsuperscript{245} the nitronium ion is about 130 ppm deshielded from NO\text{3}^-\text{ of aqueous sodium nitrate solution.}^{\text{245, 448}} \text{It has also been shown by}^{\text{14}N} \text{NMR spectroscopy that a mixture of nitric acid in 88\% sulfuric acid contains both nitronium ion and free nitric acid.}^{\text{522}} \text{At 95\% H}_2\text{SO}_4\text{ only the NO}_2^+\text{ ion was detected (a single peak at }\delta^{\text{14}N} 251\text{ relative to external liquid NH}_3\text{). Prakash, Heiliger, and Olah}^{\text{523}} \text{have recently arrived at similar conclusions through}^{\text{15}N} \text{NMR studies of the nitric acid–nitronium ion system. The}^{\text{14}N} \text{NMR spectrum of NO}_2^+\text{BF}_4^-\text{ in SO}_2\text{ solution shows a single peak at }\delta^{\text{14}N} 248.6,\textsuperscript{448} \text{whereas in 92\% H}_2\text{SO}_4\text{ it is detected at }\delta^{\text{15}N} 251.\textsuperscript{523} \text{The IGLO calculated value is }\delta^{\text{15}N} 268.3.\textsuperscript{524}

Nitronium ion, which is linear with \textit{sp}-hybridized nitrogen, is not very reactive in aprotic media and not capable of nitrating deactivated aromatics. The reactivity, however, can be increased in superacid solution (HF, HSO\text{3}F). The enhanced reactivity is attributed to protosolvation,\textsuperscript{525,526} \text{that is, to the formation of protonitronium dication NO}_2^+\text{H}_2^+\text{ (220)) suggested as early as 1975 by Olah et al.}\textsuperscript{527} \text{The interaction of the superacid with the nitronium ion weakens the N–O π-bond character resulting in the bending of the linear ion and rehybridization of the N from }\text{sp} \text{to }\text{sp}^2\text{ (220b). Early} \textit{ab initio} \text{calculations did not find a minimum for NO}_2^+\text{H}_2^+\text{, but subsequent high-level studies by Olah et al.}\textsuperscript{524} \text{(HF/6-31G* and MP2/6-31G**) showed it to be a minimum. It is characterized by a shorter N–O(1) (1.055 Å) and a longer N–O(2) (1.165 Å) bond, and an O–N–O bond angle of 172.7°. Studies by Schwarz and co-workers}\textsuperscript{528}
[RHF/6-311G** and MP2(fc)/6-311G**] resulted in similar values (1.125 Å, 1.175 Å, and 169.1°, respectively).

\[
\begin{array}{c}
\text{O} \equiv \text{N} \equiv \text{O} - \text{H} \\
\text{a}
\end{array}
\quad \leftrightarrow
\begin{array}{c}
\text{O} \equiv \text{N}^2+ \equiv \text{O} - \text{H} \\
\text{b}
\end{array}
\]

Attempts to observe ion 220 in the condensed phase under superacidic conditions were unsuccessful, but it was generated in the gas phase. However, Prakash, Olah, and colleagues made an attempt to identify ion 220 by means of \(^{17}\text{O}\) NMR spectroscopy. \(^{17}\text{O}\) enriched nitronium tetrafluoroborate, when dissolved in HSO\(_3\)F, exhibited a sharp peak at \(\delta^{17}\text{O} = 196.6\) assigned for nitronium ion \(\text{NO}_2^+\) shielded by 217.4 ppm with respect to nitric acid. Increasing the acidity by adding SbF\(_5\) to the solution (HSO\(_3\)F–SbF\(_5\) = 1:3), the \(\text{NO}_2^+\) signal moved upfield by 5 ppm and the line broadened significantly (line width = 930 Hz). This line broadening could be brought about by possible proton exchange between the acid and \(\text{NO}_2^+\) via the protonitronium dication 220, which is present in small equilibrium concentration.

The applications of nitronium salts as a synthetic reagent are discussed in Chapter 5. Until recently, the nitronium ion was recognized only as a nitrating agent. However, it has been found that it possesses significant ambident reactivity. This has been recently shown in the oxidation of sulfides, selenides, and phosphines. In fact, the sulfide reaction has been monitored by \(^{15}\text{N}\) NMR spectroscopy wherein both nitrosulfonium and nitritosulfonium ions 88 and 89 were detected as distinct intermediates [Eq. (4.147)].

\[
\begin{align*}
\text{R} = & \text{S} \quad \text{S} \quad \text{R} + \text{NO}_2^+ \quad \leftrightarrow \quad \left[ \begin{array}{c}
\text{R} \\
\text{S} \\

\end{align*}
\]

\(4.147\)

4.2.5.4. Nitrosonium Ion (NO\(^+\)). Nitrosonium ion (NO\(^+\)) 221 is an important species that is generally present in nitrous acid media. It acts as a powerful nitrosating agent of amines (both aromatic and aliphatic) resulting in the diazotization reaction [Eq. (4.148)].

\[
\begin{align*}
\text{R} = & \text{NH}_2 + \text{NO}^+ \quad \rightarrow \quad \text{R} = \text{N}_2^+ + \text{H}_2\text{O}
\end{align*}
\]

\(221\)

The first isolation of nitrosonium ion 221 as a distinct species was in the reaction of dinitrogen trioxide and dinitrogen tetroxide with boron trifluoride [Eqs. (4.149) and (4.150)].
Since then, a variety of nitrosonium salts have been isolated. The important ones are with the following counterions: BF$_4^-$, PF$_6^-$, FSO$_3^-$, HSO$_4^-$, BCl$_4^-$, and SbCl$_6^-$. The ion has been characterized by $^{15}$N NMR, IR, and X-ray analysis. A detailed NMR study by Mason and Christe have showed that conditions (solvent, counterion, temperature) have minor effects on observed $^{14}$N NMR shifts ($\delta^{14}$N 372.5–376.8).

Similar to nitronium ion, attempt was also made to identify protonated nitrosonium ion (protonitrosonium dication, HNO$_2^{2+}$) by means of $^{17}$O NMR spectroscopy. The sharp peak at $\delta^{17}$O 461.5 observed in HSO$_3$F and identified for NO$_2^+$ shifted upfield by 5 ppm upon addition of SbF$_5$. This, again, can be attributed to the presence of protonitrosonium dication in small equilibrium concentration.

The nitrosonium ion does not react toward aromatics except in activated systems. It forms a $\pi$-complex with aromatics with deep color. However, it is a powerful hydride-abstracting agent in the case of activated benzylic or allylic positions. Olah and Friedman have demonstrated that isopropylbenzenes undergo hydride abstraction to cumyl cations [Eq. (4.151)] which further reacts to give various condensation products. The reaction has been employed to prepare a variety of stable carbocations.

The unique hydride abstraction property has been gainfully employed in developing novel synthetic reactions. Reactive hydrocarbons such as triphenylmethane, adamantane, and diamantane are readily fluorinated in the presence of nitrosonium ion in HF–pyridine media. In the presence of a suitable oxygen donor such as dimethyl sulfoxide, the nitrosonium ion can act as a nitrating agent [Eq. (4.152)]. The initially formed nitrito onium ion transfer nitrates aromatics rather readily. The NO$^+$-induced reactions are further reviewed in Chapter 5.
4.2.5.5. Ammonium, Phosphonium, Arsonium, and Stibonium Ions

**Tetrahaloonium Ions.** Whereas only tetrafluoro and tetrachloro cations of N and tetrachloro and tetrabromo cations of Sb are known, all four tetrahalophosphonium and arsonium cations, along with mixed tetrahaloonium cations, have been prepared and characterized mostly by vibrational and NMR spectroscopy. In addition, X-ray crystal structure analyses have been reported for NF$_4^+$BF$_4^-$, PCl$_4^+$SbF$_6^-$, AsCl$_4^+$AsF$_6^-$, and SbCl$_4^+$SbF$_{11}^-$ Schrobilgen and co-workers have recently reported spectroscopic characterization and X-ray crystal structures of AsX$_4^+$[As(OTeF$_5$)$_6$]$^-$ (X = Cl, Br) and SbX$_4^+$[Sb(OTeF$_5$)$_6$]$^-$ (X = Cl, Br). The method of preparation is the oxidation of AsX$_3$ with XOTeF$_5$ in the presence of As(OTeF$_5$)$_n$ ($n = 4, 5$) at room temperature or oxidation of Sb(OTeF$_5$)$_3$ with X$_2$. In agreement with Raman spectroscopy data, all four cations have undistorted tetrahedral geometry in the crystal state and the anion–cation interactions are weaker than in previously known tetrahaloarsonium and tetrahalostibonium salts. By reexamining the XRD structure of NF$_4^+$BF$_4^-$, Christe et al. have recently shown that, in contrast to earlier incorrect structural analysis, the NF$_4^+$ cation is really tetrahedral. The hexafluoroarsenate of the mixed cation AsFCl$_3^+$ was also prepared and characterized.

**Acidic Onium Ions.** Relatively little is known about halogenated acidic onium ions. A few fluoroammonium salts including FNH$_3^+$HF$_2^-$,$n$HF, and F$_2$NH$_2^+$MF$_6^-$ (M = As, Sb) are known. In addition, Christe and coworkers have been able to obtain the salts ClNH$_3^+$M$^-$ (M = BF$_3$, AsF$_5$, SbF$_6$) by protonating NH$_4$Cl formed in situ from (Me$_3$Si)$_2$NCl. All salts are stable at room temperature and contain small amounts of NH$_4^+$ impurities, which prevented crystallization. IR, Raman, and NMR spectroscopy and theoretical calculations provide evidence for the existence of ion ClNH$_3^+$. For example, the $^{14}$N NMR shift at $\delta^{14}$N = 364 is only slightly deshielded in comparison with that in NH$_4^+$ ($\delta^{14}$N = 367) but considerably more shielded than that in FNH$_3^+$ ($\delta^{14}$N = 252.1).

$$\text{(Me}_3\text{Si)}_2\text{NCl} + \text{HF} + \text{M} \xrightarrow{-196 \text{ to } 25^\circ\text{C}} \text{ClNH}_3^+\text{MF}^-$$

The fluorinated salts F$_{4-n}$PH$_n^+Y^-$ ($n = 1–4$, Y = AsF$_6$, SbF$_6$, Sb$_2$F$_{11}$, Sb$_3$F$_{16}$) of phosphorus have been characterized by vibrational and NMR spectroscopy. The crystal structure of the salt PF$_3$H$^+$SbF$_6^-$HF and trihalogenphosphonium salts X$_3$PH$^+$As$_2$F$_{11}^-$ (X = Cl, Br) prepared by protonation with the corresponding conjugated superacids HF–MF$_6$ (M = As, Sb) have recently been reported by Seppelt and co-workers and Minkwitz and Dzyk, respectively. The structure of the PF$_3$H$^+$ cation is pseudo-tetrahedral and, surprisingly, the cation has no contact with either the anion or HF. The cations of the X$_3$PH$^+$As$_2$F$_{11}^-$ salts have trigonal pyramidal structure and interionic F–Cl, P–Br, and P–F contacts but F–H interactions were not detected.
Superacidic protonation of MePF₂ was also used to prepare the salts MePF₂H⁺MF₆⁻ (M = As, Sb). The cations show distorted tetrahedral structure and weak P−F interionic contacts.

Protonation of PH₃ and AsH₃ with HF was studied by conductometric measurements with the conclusion that the less basic AsH₃ is not fully protonated. After treatment in HF−TaF₅, crystalline PH₄⁺TaF₆⁻ and a mixture of AsH₄⁺TaF₁₁⁻ could be isolated. AsH₄⁺MF₆⁻ (M = As, Sb) and SbH₄⁺SbF₆⁻ were obtained by protonation of the corresponding hydrides with HF−MF₅. Me₃AsH⁺ ions were generated in a similar manner [Eq. (4.154)]. The cation in the Me₃AsH⁺As₂F₁₁⁻ salt has a trigonal pyramidal shape with weak hydrogen bonding between the hydrogen atoms of the methyl groups and fluoride atoms.

\[
\text{Me₃As} + \text{HF} + \text{MF}_5 \xrightarrow{-78^\circ \text{C}} \text{Me₃As}^+\text{MF}^- \\
M = \text{As, Sb} \quad M' = \text{As}_{2}\text{F}_{10}, \text{SbF}_5
\]  

\(\text{eq. (4.154)}\)

**Hydroxy(alkoxy)phosphonium Ions.** Olah and McFarland studied the protonation in HSO₃F or HSO₃F−SbF₅ solution of varied phosphorus oxyacids and derivatives. Treatment of tetravalent phosphorus compounds (phosphorus, phosphonic, and phosphinic acid and their trialkyl and triaryl derivatives) results in O-protonation and the formation of hydroxyphosphonium ions. Trivalent phosphites, in turn, are protonated at the phosphorus atom. The \(^{31}\text{P}\) shifts observed for the latter ions are significantly deshielded, which was attributed to significant oxonium ion character.

Minkwitz and Schneider obtained tetrahydroxyphosphonium salts by protonation of phosphorus acid with HF–AsF₅ and HF–SbF₅ [Eq. (4.155)]. XRD structure study shows that the cation of the hexafluoroantimonate salt has almost \(S_4\) symmetry and equal P−O bonds (1.529−1.536 Å). Cations and anions in the crystals are linked three-dimensionally by hydrogen bonds (each cation is bonded to six anions).

\[

\]  

\(\text{eq. (4.155)}\)

**Aurated Onium Ions.** A variety of gold ammonium cations [(AuPPh₃)₃NR]⁺ (R = Me, Et, n-Pr, isoPr, tert-Bu, cyclohexyl, Ph, Bn, 4-FC₆H₄, 4-BrC₆H₄, 4-NO₂C₆H₄) have been obtained as tetrafluoroborate salts by treating [(AuPPh₃)₃O]⁺BF₄⁻ with excess RNH₂ or RNCO. X-ray crystal structure analysis show a distorted tetrahedral geometry of the cations with the Au−PPh₃ ligands linearly coordinated to nitrogen. The cations of [(AuPPh₃)₃NR]⁺BF₄⁻ (R = tert-Bu, cyclohexyl) exhibit Au−N−Au angles smaller than the tetrahedral value (average 102°) and short Au−Au distances (~3.1 Å), indicating attractive forces between gold atoms. The cation in [(AuPPh₃)₄N]⁺BF₄⁻ shows similar features.
The powerful aurating agent [(AuPPh₃)₂O]⁺BF₄⁻ has been used by Schmidbaur et al. to generate triaurated phosphonium ions [Eq. (4.156)]. In contrast to aurated ammonium ions and as a result of the larger size of phosphorus, the Au–P–Au angle of cation 224 deviates only slightly (average 106°) from the ideal tetrahedral angle and the Au···Au distances (~3.7 Å) are significantly longer. This latter feature indicates the lack of Au···Au interactions. Cation 225 with the five-coordinate, electron-deficient central phosphorus atom was characterized by ¹H and ³¹P NMR spectroscopy. Characteristic features are a doublet (δ ³¹P 39.6) and a sextet (δ ³¹P 122) in the area ratio 5:1. Furthermore, the coupling constant is significantly reduced compared to that in 224 (J_P–P = 186 Hz versus 249 Hz), indicative of diminished s character of sp³d-hybridized P. The trigonal bipyramidal structure is suggested on the basis of C and N analogs.

\[(\text{AuPPh}_3)_3\text{O}^+\text{BF}_4^-\] 224

\[(\text{AuPPh}_3)_5\text{P}^2+\text{(BF}_4^-\text{)}_2\] 225

\[(\text{AuPPh}_3)\text{R}^+\text{BF}_4^-\] 226

The tetrafluoroborate salt of gold-arsonium cation [(AuPPh₃)₄As]⁺ (226) has also been obtained by Schmidbaur and co-workers. Surprisingly, the cation has an unusual tetragonal pyramidal structure with the Au atoms forming a slightly distorted square and the As atom occupying the apex. The Au–PPh₃ ligands coordinate nearly linearly to As and the average apical Au–As–Au angle is 70.7°. The average intramolecular Au···Au contact is 2.90 Å and intermolecular Au···Au and As···Au contacts also exist.

Other Onium Ions. Minkwitz and co-workers have obtained a variety of halophosphonium ions with a sulfur ligand including Cl₃Br₃–nPSMe⁺MF₆⁻ (n = 0–3, M = As, Sb), X₂FPSMe⁺MF₆⁻ (X = Cl, Br, M = As, Sb), and XF₂PSMe⁺Sbf₆⁻ (X = F, Cl, Br). These were prepared by methylation of the corresponding thiophosphorylhalides. Oxidative bromination, in turn, furnished Cl₃Br₃–nPSBr⁺AsF₆⁻ (n = 0–3) and Cl₃PSBr⁺Sbf₆⁻. Characterization by spectroscopic methods (vibrational, NMR) have also been reported. In addition, they have isolated the methylfluoroarsonium salts MeAsF₃⁺AsF₆⁻ and MeAsF₃⁺Sbf₆⁻.

Laali et al. have studied the protonation of tetra-tert-butyltetraphosphacubane (227a) and tetra-tert-butyltetraarsacubane (227b). In the case of tetra-tert-butyl-
tetraphosphacubane, monoprotonation was observed in FSO$_3$H or CF$_3$SO$_3$H to furnish cation 228,$^{572,573}$ whereas diprotonation occurred in the stronger superacid HSO$_3$F–SbF$_5$ (1:1) to give dication 229. The formation of a mixture of the corresponding mono- and diprotonated cations was detected when tetra-tert-butyltetrasacubane (227b) was treated in HSO$_3$F–SO$_2$.$^{574}$ The unique tetraphosphatricyclo-diene 230 also underwent similar mono- and diprotonation with FSO$_3$H and HSO$_3$F–SbF$_5$ (1:1), respectively.$^{575}$

4.3. ENIUM IONS

4.3.1. Enium Ions of Group 13 Elements

4.3.1.1. Borenium Ions. Boron cations with coordination number four such as [BH$_2$(NH$_3$)$_2$]$^+$ and many others of the type [H$_2$BL$_2$]$^+$, [HXBL$_2$], and [X$_2$BL$_2$] are well known$^{576–581}$ (X = halogen, L = electron-donating ligand). Even doubly and triply charged tetracoordinate boron cations are known. However, dicoordinate borenium ions, which are elusive and highly electrophilic species, are much less known. To date, no dicoordinate borenium ion with either only alkyl and/or aryl substituent is known. Developments in the area have been reported in reviews.$^{582,583}$

It is well recognized that electron deficiency of boron compounds can be considerably compensated by $\pi$-back bonding. Exploiting this principle, Nöth and Staudigl$^{584}$ have succeeded in obtaining borenium ions.

Reaction of anhydrous aluminum bromide with a series of 2,2,6,6-tetramethylpiperidinoaminoboron bromides in dichloromethane leads to specific displacement of bromide, which is trapped as tetrabromoaluminate. By formation of this less nucleophilic anion, and owing to the steric and electronic shielding of the $\beta$ atom by the bulky 2,2,6,6-tetramethylpiperidino moiety, dicoordinate borenium ions 231 are generated [Eq. (4.157)].

![Diagram](image2)

\begin{equation}
\text{NB} \quad \text{Br} \quad \text{AlBr}_3 \quad \text{CH}_2\text{Cl}_2 \quad \text{[231]} ^+ \quad \text{AlBr}_4^- \quad Y = \text{Me}_2\text{N}^a \quad \text{Et}_2\text{N}^b \quad \text{Me} \quad \text{Ph} \quad (4.157)
\end{equation}
Al NMR spectra confirm exclusive formation of the AlBr$_4^-$ anion, which, compared to Al$_2$Br$_6$, is characterized by its substantially sharper signal; the linewidth of $\nu_{1/2} \sim 20$ Hz in 231a and 231b corresponds to an undistorted tetrahedral AlBr$_4^-$.

The $^{11}$B NMR signals of 231 are shifted 6–18 ppm downfield relative to those of the starting compounds; their linewidths, which are greater by a factor of about 5, are consistent with a linear heteroallene structure. Also consistent with such a structure are the isotopically split IR bands at 1850–1900 cm$^{-1}$, which are assigned to an antisymmetric BN$_2$ vibration. The heteroallene structure has been confirmed by X-ray analysis of 231a.$^{585}$

Such studies have been extended to a variety of amidoborenium ions.$^{585}$ Subsequently, Parry and coworkers have isolated and characterized bis(diisopropylamino) borenium ion 232 at low temperature as tetrachloroaluminate salt.$^{586}$ Attempts to prepare the analogous bis(dimethylamino)borenium ion 233 was, however, unsuccessful.

Cations with sterically demanding tert-Bu and Me$_3$Si groups on the nitrogen atoms have been obtained by Kölle and Nöth.$^{587}$ Because of the protective bulky amino groups, the cations are stable in solution. $^{11}$B NMR spectroscopy gives resonances in the region expected for boron cations ($\delta^{11}$B 32–36), whereas IR bands around 1800 cm$^{-1}$ were assigned to B–N stretching and N–B–N bending vibrations.

Stephan and co-workers$^{588}$ have synthesized cation 234 with an extended structure containing a P=N–B=N=B moiety [Eq. (4.158)]. The crystal structure reveals a linear arrangement of the five atoms (N–B–N bond angle = 180.0°) with a B–N bond length of 1.236 Å. This bond distance is considerably shorter than those in cation 231a (1.30 and 1.42 Å) indicative of strong electron donation from the phosphinimide ligand.

\[
\begin{align*}
\text{(4.158)}
\end{align*}
\]
The chemistry of dicoordinate boron cations with additional coordinating donor ligands has also been explored.\textsuperscript{583} Three-coordinate cations \textsuperscript{235} have been reported by Jutzi et al.\textsuperscript{589} and cations \textsuperscript{236} have been synthesized by Kuhn et al.\textsuperscript{590} The X-ray crystal structure of cation \textsuperscript{237}a reported by Cowley et al.\textsuperscript{591} indicates that the 1,3,2-diazaborenium ring is planar with trigonal boron geometry (sum of angles = 359.9°) and longer B–N bond lengths (average 1.449 Å). \textsuperscript{11}B NMR spectroscopy gives a resonance at δ\textsuperscript{11}B 72, whereas calculations (B3LYP/3-21G* level) show π-interactions in the ring. Cation \textsuperscript{237}b prepared by methyl abstraction shows a resonance at δ\textsuperscript{11}B 37.1 shifted downfield substantially and a line width typical for three-coordinate boron.\textsuperscript{592} The downfield shift of the methine proton at δ\textsuperscript{1}H 6.73 coupled with the fact that cation \textsuperscript{237}b coordinates only with the strong Lewis base pyridine is indicative of a significant aromatic stabilization.

Further examples are cations \textsuperscript{238}\textsuperscript{593} and \textsuperscript{239}.\textsuperscript{594} Cation \textsuperscript{239} is particularly interesting, since the two boron substituents (phenyl and H) are barely able to contribute to π-stabilization. A broad resonance at δ\textsuperscript{11}B 38.7 in the low-temperature \textsuperscript{11}B NMR spectrum, which disappears at warming, was assigned to the trivalent B atom.

An additional \textit{n}-donor ligand results in the most stable boron cations because of the filled octet of boron and the complete coordination sphere.\textsuperscript{583} Boron in cation \textsuperscript{240} has a distorted tetrahedral geometry and a N(1)–B–C angle of 99.5°.\textsuperscript{583} In cation \textsuperscript{241} the boron atom is complexed to [Cp*Fe(CO)]\textsubscript{2}.\textsuperscript{595} The Cp* group is bonded to boron in an \textit{η}\textsuperscript{5} fashion and the Cp–B–Fe vector is essentially linear (bond angle = 177.86°). Both spectroscopic data and DFT calculations (B3LYP with LANL2DZ and 6-31 + G*
basis sets) show that the Fe–B bond order is 1.

![Image of Fe and B bond](image)

Examples of boron dications are also known. The tris(amine) dications \([X_3BH]^{2+} (PF_6)^-\) \((X = \text{pyridine}, 2\text{-Me- and 4-Me-pyridine}, 3,5\text{-diMe-pyridine})\) were synthesized by Mathur and Ryschkewitsch.\(^{596}\) Cowley and co-workers have recently succeeded in generating boron dication 242 with the coordinated bidentate base 2,2'-bipyridine\(^{597}\) [Eq. (4.159)]. The \(^{11}\text{B} \text{NMR} \) chemical shift (\(\delta^{11}\text{B} = 6.44\)) is in the range of boronium cations.\(^{583}\) The \(\text{BN}_2\text{C}_3\) ring is planar and orthogonal to the plane of the bipyridine ligand. The average bond distances (\(\text{N}–\text{C} = 1.358 \text{ Å}, \text{C}–\text{C} = 1.381 \text{ Å}\)) are identical to those of cation 237a. Since boron in 242 has a tetragonal geometry, the average \(\text{B}–\text{N}\) bond length (1.514 Å) is longer than that in the trigonal planar cation 237a (1.450 Å).

![Image of boron dication](image)

\[\text{4.3.1.2. Alumenium Ions.}\] A few examples of alumenium cations are known. Cation 243\(^{598}\) and the pentamethylcyclopentadienyl analog\(^{599}\) most likely possess \(\eta^5\)-bound metallocene-type structure. Cation 244 has been prepared from the reaction of \(\text{Et}_3\text{Al}\) with carborane trityl salts.\(^{600}\) The crystal structure of the salts 244 reveal weak bidentate interaction between the \(\text{Et}_2\text{Al}^+\) fragment and two halogen substituents of the anions. The \(\text{Al}–\text{Br}\) interactions (2.54 and 2.58 Å) are longer than typical \(\text{Al}–\text{Br}\) bonds (2.25–2.30 Å). The \(\text{C}–\text{Al}–\text{C}\) bond angles (130.0° and 136.6° for the bromo and chloro derivatives, respectively), which are larger than the ideal tetrahedral and trigonal angles suggest considerable alumenium ion character. Salts of the cation \(\text{isoBu}_2\text{Al}^+\) with the weakly coordinating anions \((\text{C}_6\text{F}_5)_4\text{M}^-\) (\(\text{M} = \text{B, Al}\)) and \([\text{Al}\{\text{OC(CF}_3)_3\}_4]^+\) have recently been

\[\text{Equation (4.159)}\]

![Image of alumenium cation](image)
The cation in \([\text{isoBu}_2\text{Al}]^{+} (\text{C}_6\text{F}_5)_4\text{B}^-\) is stabilized by two tetrahydrofuran donor ligands.

4.3.2. Enium Ions of Group 14 Elements

4.3.2.1. Silicenium Ions. One of the key intermediates that was not observed in solution for a long time is trivalent positively charged silicon, the silicenium ion \(\text{R}_3\text{Si}^+\), the analog of a carbocation.\(^{602–604}\) On the contrary, silicenium ions are well known in the gas phase as high-abundance fragments in the mass spectra of organosilicon compounds.\(^{605,606}\) The failure to observe them in solution is due to the poor ability of silicon to undergo \(p\pi–p\pi\) bonding. Whereas carbocations are readily stabilized by \(2p–2p\) resonance, the silicenium ion is more weakly stabilized through \(2p–3p\) overlap over longer bonds with lone pairs or \(p\)-electrons on carbon, nitrogen, or oxygen.\(^{607}\) Furthermore, silicon, unlike carbon, has the ability to increase its coordination number and valency, and, consequently, is prone to complexation with various nucleophiles including counterions and solvents. Moreover, the very large bond strength of silicon with oxygen, nitrogen, and most halogens make common leaving groups unavailable. This is the main reason, why attempts to prepare silicenium ions under superacidic conditions have failed (due to nucleophilic fluorosulfate or fluoride ions which strongly bond electrophilic silicon).\(^{608–611}\)

Olah and Field\(^{612}\) were able to obtain only a polarized complex \(^{245}\) from methylsilyl bromide and aluminum bromide in methylene bromide solution. However, they were able to correlate \(^{29}\text{Si}\) NMR chemical shifts with \(^{13}\text{C}\) NMR chemical shifts of analogous compounds. Based on such an empirical relationship, they have been able to predict \(^{29}\text{Si}\) chemical shift of trivalent silicenium ion.

\[
\begin{align*}
\text{Me}_3\text{Si}^+\text{Br}^- & \rightarrow \text{AlBr}_3^+ \\
\end{align*}
\]

\(^{245}\)

Later, Lambert and Schulz\(^{613}\) have prepared triisopropylthiosilicenium ion \(^{246}\) by hydride abstraction from triisopropylthiosilane using trityl perchlorate in dichloromethane solution [Eq. (4.160)].

\[
\text{(isoPr}_2\text{S})_3\text{Si}^-\text{H} + \text{Ph}_3\text{C}^+\text{ClO}_4^- \rightarrow \text{(isoPr}_2\text{S})_3\text{Si}^+\text{ClO}_4^- + \text{Ph}_3\text{CH}
\]

\((4.160)\)
The evidence for 246 comes from both electrical conductivity measurements and $^1$H and $^{13}$C NMR spectra. The IR spectrum of 246 clearly showed the presence of perchlorate anion. The $^1$H and $^{13}$C NMR data were interpreted to indicate that there is not much positive charge delocalization from silicon to sulfur. Unfortunately, the authors were not able to obtain a satisfactory $^{29}$Si NMR spectrum. Subsequently, Lambert and coworkers reported the synthesis of triphenylsilyl perchlorate\textsuperscript{614} and trimethylsilyl perchlorate\textsuperscript{615} using the same method. $^{29}$Si and $^{35}$Cl NMR spectroscopic and X-ray crystallographic studies by Prakash, Olah, and co-workers\textsuperscript{616} showed, however, that triphenylsilyl perchlorate exists as a covalent percloryl ester in both the solid state and solution. They also pointed out that existence of a silicenium ion can be proved by observing a significantly downfield shifted $^{29}$Si NMR signal. Such proof, however, did not exist.

Since the late 1980s a variety of approaches has been employed to generate silicenium ions.\textsuperscript{606,617–621} Most of the results, however, have been challenged.\textsuperscript{606,620,622–628}

Lambert and co-workers\textsuperscript{629–631} have made continued efforts to generate silicenium ions in high-polarity, low-nucleophilicity solvents (sulfolane, dichloromethane) using the hydride abstraction method with trityl perchlorate. In a subsequent study, Olah, Prakash, and co-workers\textsuperscript{622} compared experimental and computed (\textit{ab initio}/IGLO) $^1$H, $^{13}$C, and $^{29}$Si NMR chemical shifts of trimethylsilyl perchlorate and concluded that no long-lived persistent trimethylsilicenium ion was observed in solution. The $^{13}$C chemical shifts at various concentrations in sulfolane–CD$_2$Cl$_2$ reported by Lambert\textsuperscript{631} correspond closely to the calculated values of the covalent trimethylsilyl perchlorate. Furthermore, the experimentally observed $^{29}$Si chemical shift ($\delta^{29}$Si 47.0) is fundamentally different from the IGLO-calculated value of $\delta^{29}$Si 355.7.

In 1993 Lambert and co-workers\textsuperscript{632,633} reported the synthesis of the \( \text{Et}_3\text{Si}^+\text{(C}_6\text{F}_5)_4\text{B}^- \) salt [Eq. (4.161)]. It was identified as the cation 247a on the basis of a long Si–C$_\text{tolyl}$ bond distance of 2.18 Å. However, the Et$_3$Si moiety is not planar (average C–Si–C bond angle = 114°), and calculated (carbocation chemistry) bond distances and bond angles (HP/6-31G* level) are in close agreement with those found experimentally.\textsuperscript{625} Similarly, there is a particularly good agreement between the observed ($\delta^{29}$Si 81.8 in toluene\textsuperscript{632} and $\delta^{29}$Si 92.3 in benzene\textsuperscript{633}) and calculated ($\delta^{29}$Si 82.1; IGLO* at HP/6-31G* level) $^{29}$Si NMR chemical shifts, in contrast with the calculated highly deshielded shift of 355.7 ppm of the still elusive Me$_3$Si$^+$ ion. These observations and additional calculations\textsuperscript{626,634,635} showed that there is a substantial covalent bonding and substantial transfer of positive charge to toluene. Consequently, the actual species is the \textit{para}-triethylsilyltoluenium ion 247b with contribution from the resonance form 247a. According to the interpretation of Reed,\textsuperscript{636} the actual structure is not a π-arene complex nor a σ-bonded arenium ion (Wheland intermediate), but a structure in between. Additional reports about the generation of silicenium ions with a variety of weakly coordinating anions such as (C$_6$F$_5$)$_4$B$^-$.\textsuperscript{637} CB$_9$H$_4$Br$_5^-$.\textsuperscript{638} CB$_{11}$H$_4$Br$_6^-$.\textsuperscript{639,640} and 1-Me-CB$_{11}$F$_{11}^-$.\textsuperscript{641} similarly resulted in the formation of species with limited silicenium ion-like character as indicated by $^{29}$Si NMR chemical shift values in the range $\delta^{29}$Si 100–120.
A report by Jørgensen and co-workers\textsuperscript{642} about the synthesis of the first chiral tertiary alkylsilicenium ion \textbf{248} was also questioned. DFT/IGLO NMR studies showed\textsuperscript{627} that it is a silylated acetonitrilium ion. Calculations (B3LYP/6-31G\* level) to find a minimum energy structure for the free silicenium ion failed. Instead, the intramolecularly silylated spirocyclopropylarenium ion was found.

\begin{equation}
\text{Et}_3\text{Si}^+ \text{H} + \text{Ph}_3\text{C}^+\text{(C}_6\text{F}_5)_4\text{B}^- \rightarrow \text{toluene} \rightarrow \begin{array}{c}
\text{Et}_3\text{Si}^+ \\
\text{Et}_3\text{Si}
\end{array}
\end{equation}

(4.161)

\begin{figure}[h]
\begin{center}
\includegraphics[width=0.5\textwidth]{248}
\end{center}
\caption{\textbf{248}}
\end{figure}

It became clear after these efforts that the successful synthesis of free silicenium ion requires the use of a counterion as inert as possible. Furthermore, it is necessary to hinder the Si\textsuperscript{+} environment with bulky, sterically demanding groups and electronically stabilize the cation by appropriate substituents to suppress any interaction with the anion or the solvent.\textsuperscript{643,644}

Recently, Lambert and co-workers\textsuperscript{645,646} have reported the preparation of the trimesityl-substituted Mes\textsubscript{3}Si\textsuperscript{+} cation \textbf{249} using the so-called allyl leaving group approach [Eq. (4.162)] instead of the hydride transfer reaction applied in earlier studies. The electrophile attacks the double bond and the intermediate carbenium decomposes, yielding the cation.

\begin{equation}
\text{Mes}_3\text{Si}^+\text{CH}_2\text{CH} = \text{CH}_2 + \text{E}^+\text{(C}_6\text{F}_5)_4\text{B}^- \rightarrow \text{C}_6\text{D}_6, \text{RT} \\
\text{E} = \text{Et}_3\text{Si}-(\text{C}_6\text{H}_6) \quad \text{Et}_3\text{SiCH}_2\text{CPh}_2
\end{equation}

(4.162)

\begin{figure}[h]
\begin{center}
\includegraphics[width=0.5\textwidth]{249}
\end{center}
\caption{\textbf{249}}
\end{figure}
Due to the steric crowding of the mesityl groups, ion 249 is not able to react with nucleophiles or interact with the counterion or solvent. The $^{29}$Si NMR chemical shift of the ion is practically independent from the solvent ($\delta^{29}$Si 225.5–225.7). Calculations for the chemical shifts of arylsilicenium ions give values in the range $\delta^{29}$Si 226–243.9 depending on the basis sets used. X-ray crystal structure analysis of the related $\text{Mes}_3\text{Si}^+(1\text{-H-CB}_{11}\text{Me}_5\text{Br}_5)^-$ species reveals well-separated anions, cations, and solvent molecules. The silicon center is three-coordinate and planar as indicated by the sum of the three C–Si–C bond angles (120.5° + 121.7° + 117.7° = 359.9°). As expected, the Si–C bond lengths (average 1.817 Å) are shorter than those in the neutral precursor (average 1.91 Å). The mesityl groups adopt a propeller-like arrangement with twist angles 51.3, 54.5, and 41.9°, which are close to the calculated values of 47.3–49°. This allows still considerable conjugation between the aryl rings and the empty orbital of silicon. The $^{29}$Si NMR chemical shift measured in the solid state is $\delta^{29}$Si 226.7. A new silicenium ion, tris(2,3,5,6-tetramethylphenyl)Si$^+$ exhibits a similar $^{29}$Si NMR chemical shift ($\delta^{29}$Si 226.8).

Olah et al. made an unsuccessful attempt to prepare the dibenzosilatropylium ion 250 and only the corresponding covalent perchlorate ester was isolated. However, Komatsu and coworkers have recently synthesized the stable silatropylium ion 251 by hydride transfer reaction under conditions suitable for the formation of stable silicenium ions. The observed $^{29}$Si NMR chemical shift of $\delta^{29}$Si 142.9 deshielded from that of the precursor by 192.2 ppm, compares favorably with $\delta^{29}$Si 159.9, which is the calculated value [GIAO/HF/6-311 + G(2df,p)(Si), 6-31+G*/B3LYP/6-31G* level] for the idealized gas-phase structure. This indicates only small interaction between the cation and CD$_2$Cl$_2$ the solvent for NMR measurements.

The positively charged Si is similarly a part of a π-conjugated system in the homocyclotrisilylenium ion 252 [Eq. (4.163)]. The $^{29}$Si NMR resonances show that the central silicon atom is more deshielded [$\delta^{29}$Si(2) 315.7] than the terminal silicons [$\delta^{29}$Si(1) and Si(3) 77.3] and Si(4) is the most shielded [$\delta^{29}$Si(4) 15.7]. The molecular structure in the solid state shows no interaction between the cation and the benzene molecule present as solvent of crystallization. The four-membered ring is folded [dihedral angle between the planes Si(1)–Si(2)–Si(3) and Si(1)–Si(4)–Si(3) is 46.6°]. The cationic part is completely planar and Si(4) has a distorted $sp^3$ environment and the Si–Si bond lengths are between the Si–Si single and double bonds of the precursor. These features and the observation that the most deshielded Si is the central...
tricoordinated Si(2) indicate homoaromatic character with charge delocalization at Si(2).

Lickiss and co-workers\textsuperscript{653} have performed the hydride abstraction reaction shown in Eq. (4.164). On the basis of multinuclear NMR characterization, including the single sharp resonance at $\delta^{29}\text{Si}$ 17.8 observed at 60°C, the species is fluxional with rapidly equilibrating ions but with little benzenium character 253a. (Me$_3$Si)$_4$C as a byproduct (about 20\%) was also detected indicative of intermolecular Me and Ph exchange processes and intramolecular migrations. X-ray crystal studies allowed to identify the salt as the ion 253b. The phenyl group forms an almost symmetrical bridge [C$_{ipso}$–Si bond lengths = 2.104 and 2.021 Å]. The four-membered ring is folded about the Si–Si vector (dihedral angle = 13.5°). The bond distances in the aromatic ring (C$_{ipso}$–C$_{ortho}$ = 1.408 and 1.400 Å, C$_{ortho}$–C$_{meta}$ = 1.372 and 1.363 Å, C$_{meta}$–C$_{para}$ = 1.358 and 1.369 Å) show small differences, are closely similar to those of the neutral species (Me$_3$Si)$_3$CSIMe$_2$Ph, and do not show the typical long, short, long characteristic of cyclohexadienyl resonance structures. Consequently, the ion has little 253a character and better represented as structure 253b.

Ions with bridging hydrogen have also been prepared and studied.\textsuperscript{422,423,654} Common characteristics of ions 254–256 are the strong dependence of the $^{29}\text{Si}$ NMR chemical shift on the system ($\delta^{29}\text{Si}$ 99.1, 76.7, 54.4, respectively) and the markedly reduced $J_{\text{Si–H}}$ coupling constants (two doublets of heptets with $J_{\text{Si–H}}$ = 26.0 and 6.6 Hz for ion 254, $J_{\text{Si–H}}$ = 39 Hz for ion 255, and $J_{\text{Si–H}}$ = 46 Hz for
ion 256) compared to neutral silanes \(J_{\text{Si-H}} = \sim 180-200 \text{ Hz}\). Furthermore, the hydrogen in the Si–H–Si two-electron three-center bond is unusually shielded in comparison to the precursor silanes (\(\Delta \delta^1 \text{H} = -2.43\) and -1.85 for 255 and 256, respectively). Calculations at the MP2/6-31G(d,p) level\(^{422,654}\) predict a geometry that is very similar to the X-ray structure found experimentally, and computed \(\delta^{29} \text{Si}\) chemical shifts and \(J_{\text{Si-H}}\) coupling constants agree well with experimental data. Furthermore, theoretical analysis suggests very small \(3s\)-(Si)-orbital contribution to the Si–H bond, that is, the bond is almost completely of \(3p\) nature. All these data suggest that these cations have larger silicenium ion character than the corresponding halonium ions (see Section 4.2.4).

Reed and co-workers\(^{655}\) have obtained carborane salts of simple hydrogen-bridged disilyl cations 257. The X-ray structure of 257 (\(R = \text{Me}\)) confirms an essentially symmetrical cation well-separated from the anion with the following parameters: Si–H bond lengths = 1.60 and 1.62 Å, Si–Si distance = 3.1732 Å, Si–H–Si bond angle = 160°, average C–Si–C bond angle = 116.7°. The corresponding calculated data \([\text{B3LYP/6-311+G(d,p)}]\) are Si–Si = 3.82 Å, Si–H–Si = 179.7°, C–Si–C 116.0°. The \(29\)Si NMR chemical shifts (\(\delta^{29} \text{Si} 85.4\) and 82.2) are reproduced well by DFT/IGLO calculations (\(\delta^{29} \text{Si} 107\)).

Silylium ion 258 generated from perdimethylsilyl-substituted benzene by hydride abstraction is stabilized by two agostic Si–H–Si interactions.\(^{656}\) The highly decreased \(J_{\text{Si-H}}\) coupling constant of the \(\alpha\)-Si (46.3 Hz), again, is indicative of the hydrogen-bridged silylium ion, whereas the upfield shifts of the \(\alpha\)-SiH and \(\beta\)-SiH resonances (\(\delta^1 \text{H} 4.26\) and 4.41, respectively) are characteristic of agostic bondings. Ion 259 made from perdimethylsilyl-substituted toluene, in contrast, has no bridging hydrogen and exhibits resonances at \(\delta^{29} \text{Si} 34.3\) (\(\alpha\)-Si) and 33.5 (\(\beta\)-Si). The agostic interactions are also supported by DFT calculations.
Schleyer and co-workers\textsuperscript{657} and Müller et al.\textsuperscript{658} have prepared silanorbornyl cations \textbf{260} by the $\pi$-route via the intramolecular addition of the transient silicenium ion [Eq. (4.165)]. All three cations \textbf{260} exhibit strong downfield shift upon ionization ($\Delta \delta^{29}\text{Si} = 86.4–102.1$). The $^{29}\text{Si}$ NMR chemical shifts of the cations are $\delta^{29}\text{Si} = 80.2–87.2$ and agree well with calculated values ($\delta^{29}\text{Si} = 77–93$). These values are similar to those found for silabenzenium ions ($\delta^{29}\text{Si} = 70–100$), but markedly smaller than the chemical shifts for trivalent cations ($\delta^{29}\text{Si} = 225$ for $\text{Mes}_3\text{Si}^+$). The $^{13}\text{C}$ NMR chemical shift pattern of the C(3)–C(4)–C(5) saturated backbone is characteristic of the norbornyl cage. The chemical shifts for the C(6) and C(7) vinylic carbons ($\delta^{13}\text{C} = 149.6–150.6$) show a marked downfield shift relative to the precursors ($\Delta \delta^{13}\text{C} = 19.3–20.3$) indicative of the intramolecular coordination and charge transfer from Si to the vinylic carbons. The calculated structures [GIAO/B3LYP/6-311G(3d,p)//MP2/6-311G(p,d) level] support the bridged norbornyl structure of the ions.

\begin{equation}
\text{R}_2\text{HSi} + \text{Ph}_3\text{C}^+ (\text{C}_6\text{F}_5)_4\text{B}^- \xrightarrow{\text{C}_6\text{D}_6, \text{RT}-\text{Ph}_3\text{CH}} [\begin{array}{c}
\text{R}_2\text{Si} \\
\text{SiMe}_2 \\
\text{SiMe}_2 \\
\text{SiMe}_2 \\
\text{Me} \\
\text{Me} \\
\text{Me} \\
\text{Me} \\
\end{array}]^+ (\text{C}_6\text{F}_5)_4\text{B}^- \tag{4.165}
\end{equation}

Müller and co-workers\textsuperscript{659} have also attempted to generate the 7-silabenzonorbornadien-7-ylium cation \textbf{261}. However, only the corresponding nitriilium and oxonium ions, prepared in acetonitrile and diethyl ether, respectively, could be isolated, and the solvent-free ion \textbf{261} could not be detected.
The first synthesis and characterization of a persilaaromatic compound, the cyclotrisilenylium ion 262 have been accomplished by Sekiguchi and co-workers\(^1\) [Eq. (4.166)]. In the \(^{29}\)Si NMR spectrum the signals \(\delta^{29}\)Si 284.6 and 288.1 (relative intensity = 2:1) were assigned to the cationic ring Si atoms bearing the (tert-Bu)_3Si and (tert-Bu)_2MeSi substituents, respectively. The significant downfield shifts were well reproduced by calculations [GIAO/B3LYP/6-311+G(2df,p)//B3LYP/6-31G(d) level]. In the solid state, the crystals contain two molecules of toluene and the cations are well-separated from both the solvent and the anion clearly showing a free silicenium ion. The ring atoms form an almost regular triangle (internal bond angles = 59.76–60.20°) with the substituent Si atoms being in the same plane within 0.39 Å. The ring Si–Si bond distances are in the range 2.211–2.221 Å, which are intermediate between the single and double bond lengths of the precursor and agree well with the calculated value of the (HSi)_3⁺ analog of \(D_{3h}\) symmetry (2.203 Å).\(^1\)

\[\text{TSFPB} = \left[\text{4-\((\text{tert-BuMe}_2\text{Si})C_6\text{F}_4\text{)}_4\text{B}\right]\]

\[(4.166)\]

Sekiguchi and co-workers\(^1\) have performed one-electron oxidation of the precursor radical 263 to generate silicenium ion 264 [Eq. (4.167)]. In the presence of acetonitrile, the corresponding nitrile adduct was isolated, whereas in CD\(_2\)Cl\(_2\), the isomeric silicenium ion 265 was formed as a result of rapid 1,2-methyl migration from the peripheral Si to the central cationic Si atom. The observed \(^{29}\)Si NMR resonances are at \(\delta^{29}\)Si 29.1 and –69.7, and for the cationic Si atom at \(\delta^{29}\)Si 303. This value indicates that ion 265 may exist as a free silicenium ion. A temperature-dependent NMR study shows that there is a rapid exchange of Me groups through 1,3-methyl migration between the peripheral Si atoms with an activation energy of 13.1 ± 0.4 kcal mol\(^{-1}\).

\[\left[t\text{Bu}_2\text{MeSi}\right]_2\text{Si}^+ \xrightarrow{\text{Ph}_3\text{C}^+\left(C_6\text{F}_5\right)_4\text{B}^-} (t\text{Bu})_2\text{MeSi}_2\text{Si}^+ (t\text{Bu})_2\text{MeSi} \]

\[(4.167)\]

Jutzi and Bunte\(^1\) have reported the synthesis and characterization of the unusual cation 266 with divalent Si. In the \(^{13}\)C NMR spectra, one signal for the Me
and one signal for the ring carbon atoms are observed. A doublet at $\delta^{29}\text{Si} - 12.1$ in the coupled $^{29}\text{Si}$ NMR spectrum corresponds to a downfield shift of $\Delta \delta$ 386 compared to the precursor. Note that this signal is still more than 230 ppm less deshielded than the one for the Mes$_3\text{Si}^+$ ion ($\delta^{29}\text{Si} 225$). The large difference of the coupling constant of ion 266 ($J_{\text{Si-H}} = 302$ Hz) when compared to that of Cp*$_2\text{SiH}_2$ ($J_{\text{Si-H}} = 194$ Hz) indicates an increase in s-character in the Si–H bond as expected for the $sp^2$-hybridized silicon. Theoretical analysis of the parent Cp$_2\text{SiH}^+$ cation [B3LYP/6-311G(2d,p)/B3LYP/6-31G(d) + ZPVE] reveals that ion 266a of $C_2$ symmetry ($\eta^{1.5} : \eta^{1.5}$ coordination) is the most stable but ion 266b of $C_s$ symmetry ($\eta^2 : \eta^3$ bonding) is very close in energy ($\Delta E < 1 \text{ kcal mol}^{-1}$). Because the positive charge is effectively transferred to the cyclopentadienyl rings cation 266 has high thermodynamic stability. The ion is 18.7 kcal mol$^{-1}$ more stable than Me$_3\text{Si}^+$.

Another unusual cation reported by Jutzi et al. is the half-sandwich cation 267 [Eq. (4.168)]. Both salts show equivalency of all ring substituents and ring carbon atoms, respectively, in the $^1\text{H}$ and $^{13}\text{C}$ NMR spectra. Resonances in the $^{29}\text{Si}$ NMR spectra for salts 267a and 267b appear at $\delta^{29}\text{Si} - 400.2$ and $-397.4$, respectively. Such high-field shifts are characteristic of $\pi$-complexes of divalent Si. In the solid-state ion, 267a has an almost ideal pentagonal–pyramidal structure with weak interactions with the anion but no contact between Si and incorporated solvent molecules (CH$_2$Cl$_2$) is observed. The distance between Si and the center of the Cp* ring is 1.76 Å and the Si–C(Cp*) distances are in the range 2.14–2.16 Å. These distances are significantly shorter than those in the starting Cp*$_2\text{Si}$ molecule.

A related species with divalent Si is cation 268. The Si resonance in the $^{29}\text{Si}$ NMR spectrum ($\delta^{29}\text{Si} 69.3$) is indicative of strong donor–acceptor interaction of Si...
with the N ligand. The $^1$H NMR chemical shift of the $\gamma$-CH proton ($\delta^1$H 6.92) and the molecular structure of the salt suggest aromatic 6π-electron delocalization (268b).

$$\text{N} \quad \text{Si}: \quad \text{N} \quad \text{Ar} \quad \text{Ar} \quad \text{N} \quad \text{Si} \quad \text{N} \quad \text{Ar} \quad \text{Ar}$$

The high electrophilicity of the silicenium ion can be modified by intramolecular electron donation from remote substituents. Corriu and co-workers were the first to synthesize species 269 with the bidentate nitrogen ligand. Cations with other structural units and donor atoms (O, S, P) were subsequently generated. Due to the interaction called internal solvation, the silicon atom becomes pentacoordinated and largely loses its ionic character, that is, such ions differ in principle from the trivalent silicenium ions.

Finally, it is appropriate to make a short note about five-coordinate siliconium ions. The parent ion SiH$_5^+$, a penta-coordinate, tetravalent species, has been studied theoretically and by cyclotron resonance and IR spectroscopy. According to the latest computational study, the global minimum structure is of $C_s$ symmetry. Ion SiH$_5^+$ can be described as a complex between SiH$_3^+$ and H$_2$ with the hydrogen molecule bound sideways to the SiH$_3^+$ fragment. This conclusion is in agreement with spectroscopic observations.

Penta-coordinate siliconium species have been referred to as possible reactive intermediates in organic transformations. Such claims, however, were unsubstantiated. Olah, Prakash, and colleagues, in turn, reported that trialkylsilanes undergo H/D exchange of the tertiary Si–H(D) bond when treated with HI–AlI$_3$ at 0°C. This is in contrast to other HX Brønstead acids ($X = F, Cl, Br, OSO_3H, OSO_3F$) and HX–MX$_n$ conjugate acids ($X = AlCl_3, AlBr_3, BF_3, SbF_5$), which give halogen-exchanged R$_3$SiX products. The suggested mechanism of the exchange process, which includes the 2e–3c intermediate 270, is depicted in Eq. (4.169).
4.3.2.2. Germeium Ions. The allyl leaving group approach [see Eq. (4.162)] has been successfully applied to the synthesis of the ion $\text{Mes}_3\text{Ge}^+$, the germanium analog of ion $\text{249}$. Since Ge lacks a sensitive and convenient nuclide, there is no easy and direct NMR method to assess the germeium ion character of the species isolated. Nevertheless, a comparison of the $^{13}$C NMR chemical shifts with those of the analogous Si and Sn ions indicates comparable cationic character.

Sekiguchi and co-workers have recently generated numerous germeium ions of varied structures. Cation $\text{271}$ is formed as a result of an unexpected rearrangement of the initially formed intermediate germeium ion $\text{271}$. According to the $^1$H NMR spectrum, the three tert-butyl groups are nonequivalent and one shows hindered rotation. The $^{13}$C NMR chemical shift of C(2) of one of the phenyl groups ($\delta^{13}$C 102.8) is upfield by about 25 ppm relative to the C(2) carbons of the other two aromatic rings ($\delta^{13}$C 130.3 and 126.3). In contrast, the other carbons are shifted downfield. These changes are close to those calculated for the $\text{Me}_3\text{Si}^+$–benzene complex. Consequently, in cation $\text{271}$ the Ge$^+$ ion is intramolecularly coordinated to the C(2) atom of the aromatic ring which has a weak arenium ion character.

One-electron oxidation of the isolable Ge-centered radical results in the formation of the corresponding germeium cation $\text{272}$ [Eq. (4.171)]. Because of its highly symmetric nature, cation $\text{272}$ exhibits simple NMR spectra. The resonances of Me groups attached to Si ($\delta^1$H 1.17) and the Si signals ($\delta^{29}$Si 49.9) are highly deshielded, which are indicative of the positive charge transferred from Ge to the electropositive Si atom. Indeed, DFT calculations [B3LYP/6-31G(d) level] on the compound ($\text{H}_3\text{Si}$)$_3\text{Ge}^+$ show the following charge distribution: Ge = $-0.12$, Si = $+0.37$. In the
solid state, the Ge center has a completely planar geometry with very long Ge—Si bonds (average bond distance = 2.5195 Å).

Using the method applied for the preparation of the persilaaromatic ion 262 shown in Equation (4.166), Sekiguchi and co-workers have succeeded in obtaining the corresponding Ge analogs 273. According to X-ray crystal structure analysis of 273a and 273b (Y = TFPB or TSFPB), the Ge atoms form an equilateral triangle (Ge—Ge bond lengths = 2.321–2.335 Å, Ge—Ge—Ge bond angles = 59.8–60.3°) with the Si atoms lying approximately in the same plane. The Ge—Ge bond distances are intermediate between Ge—Ge single (2.522 Å) and Ge—Ge double bonds (2.239 Å). The Ge—Ge bond lengths agree well with that calculated for the (HGe)₃⁺ analog of D₃h symmetry (2.361 Å).

There is no significant interaction between the cation and the counterion. The characteristic NMR features are practically the same for cation 273b with all three anions and independent from the solvents used. The ²⁹Si NMR resonances are shifted downfield (δ²⁹Si 37.2 for the tert-Bu₃Si attached to the saturated Ge atom and 50.1 for the tert-Bu₃Si attached to the Ge=Ge double bond) relative to the neutral precursor, which indicates significant charge transfer from Ge to Si. The Mulliken charges (Ge = −0.07, Si = +0.64) are in harmony with this observation.

Two other germenium ions obtained by Sekiguchi and co-workers are the bishomoaromycyclopropenylium ion 274 and the cation cluster 275 with trishomoaromaticity. Cation 274 is free in the solid state and forms a Ge₃ equilateral triangle and a Ge₂C₂ four-membered ring. The Ge(3)—C(1) and Ge(3)—C(2) distances are short (2.415 and 2.254 Å), whereas the C=C double bond is long (1.411 Å) because of through-space interaction and effective homoconjugation. This results in a significant bending of Ge(3) toward the C=C double bond [dihedral angle between the Ge(1)—Ge(2)—Ge(3) and Ge(1)—Ge(2)—C(1)—C(2) planes = 67°] and a slight pyramidalization of the Ge(3), C(1), and C(2) atoms. Cation 274 shows the characteristic deshielded ²⁹Si NMR resonances (δ²⁹Si 56.1 and 67.2) and considerably shielded ¹H chemical
shift of the proton attached to C(2) and $^{13}$C NMR shifts of the C(1) and C(2) atoms relative to the precursor.

The structure of cation 275 was characterized by X-ray crystallography and multinuclear NMR spectroscopy. The cluster of 10 Ge atoms has an approximate $C_3v$ symmetry. The Ge-Ge bond distances of unsubstituted Ge atoms [G(1), G(2), and G(3)] in the central Ge$_3$ core (3.2542–3.2642 Å) are longer than the other Ge-Ge bonds in the cluster (2.4711–2.5449 Å), but they are in the range of metallic Ge-Ge bond lengths. A DFT calculation [B3LYP/6-31G(d) level] on the compound Ge$_{10}$H$_7^+$ gives the cluster skeleton of cation 275 as the global minimum structure. Molecular orbital calculations indicate bonding interactions between the three Ge atoms in the core and show that the positive charge is evenly distributed over these atoms, indicating the formation of a 2e–3c bond. The calculated aromatic stabilization energy of $-19.2$ kcal mol$^{-1}$ indicates a large homoaromatic stabilization.

The characteristic structural features of two-coordinate low-valent germanium cation 276 are similar to those of the analogous Si cation 268 discussed above. The average C–N and C–C bond distances (1.348 Å and 1.392 Å, respectively) and the essentially planar ring indicate aromatic delocalization. In contrast, however, the γ-CH proton ($\delta^1$H 4.23) is more shielded. The aromatic substituents are perpendicular to the GeN$_2$C$_3$ plane.

4.3.2.3. Enium Ions of Other Group 14 Elements. Stannylium ions obtained in early studies by Birchall and Manivannan (Me$_3$Sn$^+$FSO$_3^-$), Lambert and Kuhlmann$^{693}$ [Bu$_3$Sn$^+$H(C$_6$F$_5$)$_3$B$^-$], and Kira et al.$^{694}$ (Bu$_3$Sn$^+$TFPB$^-$) exhibit $^{119}$Sn NMR chemical shifts in the region $\delta^{119}$Sn 322–360. Using the empirical correlation
between $^{29}\text{Si}$ and $^{119}\text{Sn}$ chemical shifts, Arshadi et al. concluded that these claimed stannylium ions have, in fact, little ionic character (assuming linear relationship between $^{29}\text{Si}$ and $^{119}\text{Sn}$ chemical shifts, the chemical shift of $^{29}\text{Si} 225$ corresponds to $^{119}\text{Sn} 1100$). However, using the approach, which finally led to the preparation of the first long-lived bona fide silicenium cations, Lambert et al. succeeded in synthesizing the stannylium cation ($\text{Mes}_3\text{Sn}^+$) analogous to silicenium ion $^{249}$. The $^{119}\text{Sn}$ NMR chemical shift value at $^{119}\text{Sn} 806$ observed for the ion $\text{Mes}_3\text{Sn}^+ (\text{C}_6\text{F}_5)_4\text{B}^-$, although compares favorably with the calculated value ($^{119}\text{Sn} 1100$), indicates that the cationic character of the ion is smaller (about 75%) than that of silicenium ion $^{249}$. Other stannylium ions, phenylbis(2,4,6-triisopropylphenyl)Sn$^+$ and tris(2,3,5,6-tetramethylphenyl)Sn$^+$, exhibit even lower shift values ($^{119}\text{Sn} 697$ and 720). Subsequently, Michl prepared the cations $\text{Me}_3\text{Sn}^+$ and $\text{Bu}_3\text{Sn}^+$ and obtained the crystal structure of $\text{Bu}_3\text{Sn}^+ \text{CB}_{11}\text{Me}_{12}^-$. The geometry around the tin, however, was found to be nonplanar (sum of C–Sn–C bond angles $= 353.1^{\circ}$) and the cation weakly coordinated to the anion. Furthermore, the $^{119}\text{Sn}$ NMR chemical shifts of these cations are much smaller ($^{119}\text{Sn} 335.9$ for $\text{Me}_3\text{Sn}^+$ and 454.3 for $\text{Bu}_3\text{Sn}^+$) than those mentioned above. Lambert et al. succeeded in obtaining the crystal structure of tris (2,4,6-triisopropylphenyl)Sn$^+ (\text{C}_6\text{F}_5)_4\text{B}^-$. Although the chemical shift value is also low ($^{119}\text{Sn} 714$; the value calculated by the GIAO method is $^{119}\text{Sn} 763$), the cation has a practically planar geometry (sum of C–Sn–C bond angles $= 359.9^{\circ}$). Sekiguchi et al. have prepared the cation [(tert-Bu)$_2\text{MeSi}]_3\text{Sn}^+$ the tin analog of cation $^{272}$ using the one-electron oxidation method [see Eq. (4.171)]. X-ray analysis shows that the Sn ion has a perfectly planar geometry (sum of the bond angles around Sn is 360.0$^{\circ}$) and the Me substituents of Si atoms lie in the same plane. An unexpectedly high $^{119}\text{Sn}$ NMR chemical shift at $^{119}\text{Sn} 2653$ was observed. This value greatly exceeds those observed earlier for any stannylium ion and the estimate given by Arshadi using the empirical correlation with $^{29}\text{Si}$. However, it agrees well with the value of $^{119}\text{Sn} 2841$ calculated for the model parent ion ($\text{H}_3\text{Si})_3\text{Sn}^+$. In addition to the silanorbornyl cations $^{260}$ [see Eq. (4.165)], Müller et al. obtained the corresponding Ge and Sn ($R = n$-Bu), and Pb ($R = \text{Et}$) analogs. The downfield shift of the C(6) and C(7) vinylic carbons is also observed for the Ge, Sn, and Pb cations, but the values are smaller and they decrease from Si to Sn ($\Delta^{13}\text{C} 19.3–20.5$ for Si cations, 14.6 for Ge, 11.1 for Sn, and 7.8 for Pb). This shows that electron transfer from the C = C double bond to the metal decreases from Si to Sn. The Pb center is less deshielded ($^{207}\text{Pb} 1049$) than those in other triorganolead ions (for example, $^{207}\text{Pb}$ for [Et$_3$Pb-C$_6$D$_6$]$^+$ (C$_6$F$_5)_4\text{B}^-$ is 1432$^{520,658}$ and the same is observed for the Sn ion ($^{119}\text{Sn} 334$ versus 806 for Mes$_3\text{Sn}^+$). Additionally, the coupling constants between vinylic carbons and Sn or Pb are reduced by about an order of magnitude ($J_{\text{C–Sn}} = 26 \text{ Hz}, J_{\text{C–Pb}} = 16 \text{ Hz}$), suggesting a direct bonding.

The plumbylium cation $^{277}$ is an intramolecular bisalkene complex and can also be considered as a spironorbornyl cation $^{200}$ [Eq. (4.172)]. The $^{13}\text{C}$ NMR spectrum (only six resonances) suggests that the cyclopentenemethyl substituents are equivalent and symmetrically situated. Other spectral characteristics are similar to those of related norbornyl cations of Group 14 elements already discussed. The vinylic carbons are downfield-shifted ($\Delta^{13}\text{C} 5.9$), the C–Pb coupling constant is significantly reduced.
\( J_{C-Pb} = 14.4 \text{ Hz} \), and the \(^{207}\text{Pb} \text{ NMR resonance is strongly downfield-shifted relative to the precursor (\( \delta^{207}\text{Pb} 807, \Delta\delta^{207}\text{Pb} 777 \)) but less deshielded than in other triorganolead ions. Anions and cations are well-separated in the solid state and the trigonal base is planar (sum of \( \text{C-Pb-C} \) bond angles = 360.0°). The Pb has a distorted trigonal–bipyramidal geometry with the double bonds in apical position but tilted by 14° toward the \( \text{C}_3\text{Pb} \) plane. According to calculations [\( \text{MP2/6-31G(d,p)(C,H)} \), SDD (Pb)//\( \text{MP2/6-31G(d)} \) SDD(Pb)] the intramolecular interactions stabilizes the ion by about 28.3 kcal mol\(^{-1}\).

\[
\begin{align*}
\text{Et}_2\text{Pb} & \quad \text{Ph}_3\text{C}^+ (\text{C}_6\text{F}_5)_4\text{B}^- \\
\text{C}_6\text{D}_5\text{CD}_3 - \text{Ph}_3\text{CH}, -\text{C}_2\text{H}_4 & \quad \text{Et}^+ (\text{C}_6\text{F}_5)_4\text{B}^- (4.172)
\end{align*}
\]

In the synthesis of cation 277 the cation 278 was also isolated as a byproduct. \(^{13}\text{C} \text{NMR data show that all three cyclopentenemethyl substituents are equivalent at the NMR time scale, suggesting a dynamic equilibrium between bisalkene complexes.} \]

The tin analog of ion 267a [see Eq. (4.168)] has been prepared and a \(^{119}\text{Sn} \text{ NMR chemical shift at } \delta^{119}\text{Sn} -2219 \text{ was reported.} \]

4.3.3. Enium Ions of Group 15 Elements

4.3.3.1. Nitrenium Ions. Nitrenium ions containing positive nitrogen have been postulated as intermediates in rearrangement, synthesis, and cleavage of nitrogen-containing organic compounds. Arylnitrenium ions have recently attracted considerable interest because of their suspected role in chemical carcinogenesis. In contrast to a trivalent carbocation, the nitrenium ion 279 is unusual in that it has both a positive charge and a nonbonding pair of electrons [Eq. (4.173)]. Hence, the nitrenium ion could exist both as a singlet (279a) and a triplet (279b). The singlet would
resemble a carbocation and the triplet a radical cation with great tendency for hydride abstraction.

Quantum-chemical calculations for a wide variety of nitrenium ions are abundant.\textsuperscript{704} For the parent H$_2$N$^+$ ion the triplet state was found experimentally to be more stable by 30 kcal mol$^{-1}\textsuperscript{704}$ The H–N–H angle in the triplet is calculated to be considerably greater (149.4 versus 107.1\textdegree).\textsuperscript{705} The infrared spectrum of the complex He–H$_2$N$^+$ has also been observed.\textsuperscript{706}

Attempted generation of nitrenium ions as distinct species under long-lived stable ion conditions has thus far been unsuccessful.\textsuperscript{707–710} Protonation of nitroso benzenes in superacid media, for example, has led only to benzenium-iminium dications \textsuperscript{280} [Eq. (4.174)].

One exception is the trifluorodiazenium ion N$_2$F$_3$$^+$ \textsuperscript{281}, which could be considered as a potential nitrenium ion. Christe and Schack\textsuperscript{711} have obtained N$_2$F$_3$$^+$ \textsuperscript{281} by the ionization of tetrafluorohydrazine in HF–SbF$_5$ solutions [Eq. (4.175)]. Similarly, they have been successful in preparing pentafluorostannate and hexafluorostannate salts. The vibrational and \textsuperscript{19}F and \textsuperscript{15}N NMR spectroscopic data\textsuperscript{448,711} are consistent with planar structure \textsuperscript{281a} with $C_s$ symmetry with very little nonplanar nitrenium ion (\textsuperscript{281b}) character of $C_1$ symmetry.

Recently, persistent nitrenium ions—including the triazolinium ion \textsuperscript{282}, which is considered a nitrenium ion on the basis of the resonance form \textsuperscript{282b}—have been
isolated and structurally characterized by X-ray crystallography.\textsuperscript{712} The N–N bond distances were found to be equal (1.286 Å) and distinctly shorter than those in an 1,2,3-triazole studied for comparison (1.375 and 1.302 Å).

\begin{center}
\includegraphics[width=0.5\textwidth]{282.png}
\end{center}

The ambivalent nature of an \( \alpha \)-cyano group on a carbocationic center has been demonstrated by the solvolytic work of Gassman and co-workers.\textsuperscript{713,714} Inductively, the cyano group strongly destabilizing. However, the major portion of this effect is offset by the mesomeric nitrenium ion structure \textsuperscript{283b}.

\begin{center}
\includegraphics[width=0.5\textwidth]{283.png}
\end{center}

Olah et al.\textsuperscript{715,716} have prepared a series of \( \alpha \)-cyanodiarylcarbenium ions \textsuperscript{283} (R = Ar) under superacidic conditions and have evaluated their mesomeric nitrenium ion character by \(^1\)H, \(^13\)C, and \(^15\)N NMR spectroscopy. A subsequent one-bond \(^13\)C–\(^13\)C coupling constant measurement\textsuperscript{717} also indicates significant mesomeric nitrenium ion character of \textsuperscript{283} (R = Ar). Protonated aroyl cyanides \textsuperscript{284}, however, exist predominantly in the carboxonium ion form of \textsuperscript{284a} over the nitrenium ion form \textsuperscript{284b}.\textsuperscript{718}

\begin{center}
\includegraphics[width=0.5\textwidth]{284.png}
\end{center}

\subsection*{4.3.3.2. Phosphenium Ions.} In contrast to widely studied phosphonium ions (\( R_4P^+ \)), the chemistry of the dicoordinate phosphenium ions was little known,\textsuperscript{719} but there have recently been significant developments.\textsuperscript{720–722} It has been recognized that phosphonium ions can only be generated if one of the substituents is a dialkylamino group\textsuperscript{723} [Eq. (4.176)]. Obviously, these ions are stabilized by the strong electron-donating amino function directly attached to phosphorus. On the
other hand, the iminium ion character (285b) compromises their phosphonium ion character (285a).

\[
\begin{align*}
R_2N_\text{P} - \text{Cl} + 0.5 \text{Al}_2\text{Cl}_6 & \rightarrow R_2N^+\text{PAlCl}_4^- \\
\text{R} &= \text{alkyl, } \text{Me}_3\text{Si} \\
\text{R}' &= \text{Me}_2\text{N}, (\text{Me}_3\text{Si})_2\text{N}, \text{Me}_3\text{C}, \text{Cl}
\end{align*}
\]

Parry and co-workers\(^\text{724,725}\) have carried out detailed \(^{31}\text{P}\) NMR spectroscopic study of a series of phosphonium ions. Their study indicates that the chemical shift of the P\(^+\) center depends upon the steric crowding around phosphorus and the extent of back-donation from the nitrogen lone pair. In the case of tert-butyldimethylaminophosphonium ion 286a the \(^{31}\text{P}\) chemical shift of the P\(^+\) center is at \(\delta^{31}\text{P} 510\) (from 85\% H\(_3\)PO\(_4\)), and it appears to be the largest-ever \(^{31}\text{P}\) downfield shift to be measured. On the other hand, bis(dimethylamino)phosphonium ion 286b shows a chemical shift of \(\delta^{31}\text{P} 264\). Two-coordinate geometry of phosphonium ions has been confirmed by X-ray diffraction studies on the tetrachloroaluminate salt of cation 286b with a N–P–N angle of 114.8°.\(^\text{726}\)

Structurally related cations are cyclic phosphonium ions 287,\(^\text{727,728}\) 288,\(^\text{728–731}\) 289,\(^\text{732–734}\) and 290\(^\text{735}\) with an NPN moiety. No interionic contacts were observed in the crystals of hexafluorophosphate, tetrafluoroborate, and triflate salts of cations 288. The planar ring structure and the ring bond distances being intermediate between single and double bonds lent evidence for \(\pi\) electron delocalization. This, however, is only a weak delocalization and the cations cannot be described as genuine aromatic systems.\(^\text{730}\)
Veith et al.\textsuperscript{736} have prepared the unique four-membered cyclic phosphonium ion \textsuperscript{291}. X-ray crystal structure analysis of the tetrachloroaluminate salt clearly indicates the intramolecular backbonding from ring nitrogen atoms (average N–P bond distance = 1.633 Å).

\[
\begin{array}{c}
\text{tertBu--N--Si--N--tertBu} \\
\end{array}
\]

\textsuperscript{291}

The phosphonium ion \textsuperscript{292} with a P–C σ-bond has been isolated and structurally characterized by X-ray crystallography.\textsuperscript{737} The loss of electronic stabilization upon the replacement of a dialkylamino group is countered by kinetic stabilization by the bulky mesityl substituent in ion \textsuperscript{292}. The \textsuperscript{31}P NMR resonance of the ion is at δ\textsuperscript{31}P 500 (368 ppm downfield from that of the parent chlorophosphine). As a rare example, the \textsuperscript{31}P signal is a triplet due to coupling to the quadrupolar \textsuperscript{14}N (J\textsubscript{P–N} = 65 Hz). A notable feature of the X-ray structure is the N–P bond distance (1.617 Å), which is, surprisingly, not different from those found in ion \textsuperscript{286c} (1.611 and 1.615 Å), where the double-bond character is distributed over two dialkylamido substituents. The P–C bond length (1.787 Å) is of single-bond character, although it is relatively short for P(III) (the P–C bond length in the neutral parent chlorophosphine is 1.848 Å, the P–C double bond in a phosphaalkene is 1.684 Å). The mesityl group is rotated out of the NPC(1)C(2) plane by 69°, which prevents any conjugation with the aromatic π system. Interestingly, the N–P–C(3) angle is only 107.0°, that is, significantly smaller than the N–P–N angle in ion \textsuperscript{286b} (114.8°). The unique ferrocenyl-stabilized two-coordinate phosphonium ion \textsuperscript{293} was also prepared and analyzed.\textsuperscript{738}

\[
\begin{array}{c}
1 \quad N \quad P \quad 3 \\
2 \quad \text{AlCl}_4^- \\
\end{array}
\]

\textsuperscript{292}

Phosphonium ions can also be stabilized by intramolecular coordination to a Lewis base. In ion \textsuperscript{294}, which was prepared by hydride abstraction\textsuperscript{739} [Eq. (4.177)], intramolecular bis-coordination exists. The \textsuperscript{31}P NMR spectrum of the corresponding P–H derivative\textsuperscript{740} exhibits one doublet at δ\textsuperscript{31}P 37.6 (J\textsubscript{P–N} = 243 Hz). The X-ray structure, which shows no interaction between the cation and the hexafluorophosphate anion, clearly demonstrates an ionic structure. Both arms are coordinated to the phosphorus center. The N–P distances are 2.082 and 2.068 Å, which are longer than the N–P σ-bond (1.769 Å) but significantly shorter than the sum of the two van der
Waals radii (3.4 Å). The P−H bond is almost orthogonal to the plane of the benzene ring \( (C_{ipso}−P−H \) bond angle = 99.4°). The phosphorus atom has a distorted trigonal bipyramid with the amino groups occupying the axial sites and \( C_{ipso}, H \), and the phosphorus lone pair occupying the equatorial sites.

\[
\text{In cation 295 analogous to borenium ion 236, both an N directly attached to P and a donor nitrogen ligand contribute to stabilization.}^{741} \text{ Ion 296, in contrast, is N, C-bonded.}^{742} \text{ A single-crystal X-ray diffraction study of 296 (} R = \text{Cl, } Y = \text{TfO} \text{) reveals a hydrogen bond between the triflate oxygen and the nonligated nitrogen. The six-membered ring adopts an envelope conformation with a nearly planar P−N (1)−C(2)−C(3)−C(4) moiety and a flip of C(5) by 45.99°. Bond distances are indicative of considerable electron delocalization.}
\]

\[
\text{Considering the observation}^{743} \text{ that the stabilizing effect of donor substituents decreases in the order } \text{NH}_2 > \text{SH, OH > Cl}, \text{ it is not surprising that examples of cations with oxygen as directly attached donor atoms, such as cation 297, are scarce.}^{744} \text{ Cation 298 with sulfur as an intramolecular } n\text{-donor is the only example of its kind.}^{745}
\]

\[
\text{Di- and triphosphonium ions have also been synthesized and characterized. The 299 phosphanyl phosphonium ion was generated by a large excess of methyl triflate}^{746}
\]
Creation of the positive charge brings about a considerable low-frequency shift of both $^{31}$P NMR resonances (from $\delta^{31}$P 495 of the precursor to two doublets at $\delta^{31}$P 237 and 332.2). The phosphorus center P(1) is trigonal planar, and there is no twist around the P–P double bond. The only notable change in the X-ray characteristics upon methylation is the enlargement of the P(1)–P(2)–C$_{ipso}$ bond angle (102.8 versus 123.1°). These features indicate that the ion has a low phosphonium ion (299a) character.

The mixture of Ph$_3$P and AlCl$_3$ reacts with PCl$_3$ to yield the 300 triphosphonium ion.$^{747}$ [Eq. (4.179)]. There are two independent, yet not significantly different cations in the crystal. The P–P distances (2.128 and 2.137 Å, and 2.124 and 2.141 Å) lie between that of a P–P single bond (2.20–2.25 Å) and a P = P double bond (2.00–2.05 Å).

$$\text{PCl}_3 + 3\text{Ph}_3\text{P} + 2\text{AlCl}_3 \xrightarrow{\text{CHCl}_3, 3^\circ \text{C}} [\text{Ph}_3\text{P} - P - \text{Ph}_3\text{P}]^+ \text{AlCl}_4^- + \text{Ph}_3\text{PCl}^+ \text{AlCl}_4^-$$  

(4.179)

The cation 301 with homoatomic P=P coordination has been shown to be better represented by resonance structure 301b.$^{727}$ In contrast, cations 302 and 303, as well as dications 304 obtained by Burford et al.,$^{748,749}$ have been characterized as diphosphines linked to one or two R$_2$P$^+$ Lewis acid units. The P of phosphine ligands has distorted tetragonal geometry and the geometry of P$^+$ is distinctly pyramidal with standard phosphine-like bond angles (90–105°). Furthermore, all cations exhibit strikingly uniform P–P bond distances (2.187–2.230 Å for monocations and 2.163–2.233 Å for dications). The salts are R$_2$P$^+$ cation donors in ligand exchange reactions.
Attempts have been made to observe bisphosphenium dications [Eq. (4.180)] and trisphosphenium trications [Eq. (4.181)]. In all cases, however, only monoionization takes place.

\[
\begin{align*}
\text{\ce{\text{P}N\text{P}}} & \quad \text{\ce{\text{P}N\text{P}}} + 2\text{AlCl}_4^- + 2\text{Al}_2\text{Cl}_6 \\
\text{Cl-P-P-Cl} & \quad \text{Cl-P-P-Cl} + \text{Al}_2\text{Cl}_6
\end{align*}
\]

(4.180)

\[

\end{align*}
\]

(4.181)

Laali, Regitz, and co-workers have reported the first synthesis and characterization of a phosphirenylium ion. Cation 305 was obtained by exploiting the super Lewis acidity of B(OTf)_3 [Eq. (4.182)]. The single phosphorus resonance in the $^{31}$P NMR spectrum at $\delta^{31}$P 309.7 is deshielded by 313 ppm from the precursor, indicating the cationic character of the P atom. Both $^1$H and $^{13}$C NMR spectral data of all ring atoms show downfield shifts indicative of charge delocalization over the ring. The $^{13}$C NMR phenyl resonances are also deshielded, suggesting that charge delocalization to the aromatic ring also takes place. \textit{Ab initio} calculations (HF/6-31 + G* level) show that bonds are delocalized (P−C and C−C bond orders are 0.980 and 1.776, respectively).

\[
\begin{align*}
\text{\ce{\text{Ph-P-OOSCF}}} & \quad \text{\ce{\text{B(OTf)}_3}} \\
\text{SO}_2 & \quad \text{\ce{\text{SO}_2}}
\end{align*}
\]

(4.182)

Regitz and co-workers have recently reported the phosphirenylium ion 306 complexed to W(CO)_5. Similar to ion 305, the formation of cation 306 is characterized by a significant downfield shift of the $^{31}$P NMR resonance (about 300 ppm). NMR spectroscopic data, in general, exhibit close resemblance to the values of the non-complexed ion 305. The prototype aromatic phosphirenylium ion cyclo-C$_2$H$_2$P$^+$ 307 has been generated in the gas phase and characterized using collision-induced
dissociation (CID) spectra. DFT calculations (B3LYP/6-31G* and G3/B3LYP/6-31G* levels) have found that the ion 307 is the lowest energy structure of 10 possible isomers.

4.3.3.3. Enium Ions of Other Group 15 Elements. Similar to phosphenium ions, amino group(s) directly attached to arsenic or antimony provide stabilization through strong electron donation (308–311). Interestingly, however, in the AlCl₄⁻ salts of the stibium and bismuth analogs of ion 291, the origin of stabilization is a strong interionic interaction between Sb⁺ and Bi⁺, respectively, and the chlorine atoms of Al (Sb—Cl = 3.05 Å, Bi—Cl = 3.09 Å). The As and Sb analogs of 289 and 290 have also been prepared and characterized. Diphosphane donors may also stabilize arsenium cations as shown by the synthesis of [(Me₂N)₃PAsP(NMe₂)₃]⁺BPh₄⁻.

Chloride abstraction from the corresponding precursors of identical structure has resulted in the formation of the amidocyclopentadienyl As and Sb cations 312 and 313 with different structures. In both cases ³¹P NMR spectra show a downfield shift. Single crystal structure of the arsenium cation 312 reveals a modest increase in the N—As—C angle and decrease in the As—N and As—C bond lengths. In contrast to the η¹(σ) attachment found in cation 312, the stibenium cation 313 has a η³ bonding to the cyclopentadienyl ring. An additional noteworthy feature is the shortening of the N—Sb bond by about 0.2 Å indicating a more significant electron donation.
Intramolecular coordination to a Lewis base such as in cation 314 likewise contributes to the stabilization of arsenium ion. Examples for intermolecular complexation are more numerous. X-ray crystal structure analysis of cations 315 and 316 reveals similar features to those of the corresponding phosphenium ions discussed above. The dimeric cation 317 is unique since it is stabilized by both the amino group attached directly and through intermolecular coordination. In the stibenium cation 318, the stereochemistry around antimony is trigonal pyramidal with the antimony at the center of the trigonal plane containing the two phenyl groups and the lone pair of electrons of the six-electron Ph₂Sb⁺ group. The Me₃P moiety lies directly above the antimony atom and is orthogonal to the trigonal plane. In the solid state, four cationic units surround a central chloride or bromide ion in a centrosymmetrical, square-planar arrangement of C₄h symmetry. The Sb–Cl and Sb–Br contacts are 3.1362 and 3.2236 Å (sums of the van der Waals radii for the two elements are 3.87 and 4.24 Å, respectively).

4.3.4. Enium Ions of Group 16 Elements

4.3.4.1. Oxenium Ions. Oxenium ions similar to nitronium ions are, in general, too reactive to be observed. The parent ion—that is, the hydroxyl cation HO⁺—is elusive, and it is improbable that it can be observed in its “free” form in the condensed state. However, the incipient hydroxyl cation is involved in acid-catalyzed electrophilic hydroxylation with protonated (or Lewis acid complexed) hydrogen peroxide (HO–OH₂⁺) or ozone (HO–O–O⁺). Nitrous oxide is also a potential precursor for the hydroxyl cation (in its protonated form). The hydroxy diazonium ion HON₂⁺ has not yet been observed.

Alkyl- and aryloxenium ions (RO⁺) are similarly too reactive to be observed; however, they may be involved in the oxidation of alkanes under superacidic
conditions with ozone (see Section 5.12.2). Of all the possible alkyloxenium ions, the tert-butyloxenium ion is the most significant. Superacid cleavage of tert-butyl hydroperoxide in a Hock-type reaction gives acetone and methyl alcohol, indicative of the intermediacy of the tert-butyloxenium ion [Eq. (4.183)]. Under stable ion conditions even at low temperatures, only the rearranged carboxonium ion could, however, be observed.

\[
\begin{align*}
\text{Me}_3\text{C} - \text{OOH} & \xrightleftharpoons{\text{H}^+} \text{Me}_3\text{C} - \text{O}^+ \xrightarrow{\text{-H}_2\text{O}} \text{Me}_3\text{C} - \text{O}^+ + \text{H}_2\text{O} \\
& \xrightarrow{\text{Me}_3\text{C} - \text{O}^+} \xrightarrow{\text{Me}_3\text{C} - \text{C} = \text{O}^+} \xrightarrow{\text{Me}_3\text{C} - \text{O}^+} \text{Me}_3\text{C} - \text{C} = \text{O} + \text{MeOH}
\end{align*}
\]

(4.183)

Similarly, the cumyloxenium ion is involved in the acid-catalyzed cleavage rearrangement reaction of cumene hydroperoxide to phenol and acetone [Eq. (4.184)].

\[
\begin{align*}
\text{Ph} & \xrightarrow{\text{H}^+} \text{Ph}^+ \xrightarrow{\text{-H}_2\text{O}} \text{Ph}^+ + \text{H}_2\text{O} \\
& \xrightarrow{\text{Ph}^+} \xrightarrow{\text{Ph}^+} \xrightarrow{\text{Ph}^+} \text{PhOH} + \text{CO}
\end{align*}
\]

(4.184)

Aryloxenium cations, however, can be best regarded as cyclohexadienyl ions because of strong delocalization. The lifetime of cation in water was estimated to be 0.55 μs. Properties of phenyloxenium and phenylnitrenium ions have been calculated (HF/6-31G* and pBP/DN/*//HF/6-31G* levels). Both ions are ground-state singlets and stabilized by 4-methyl and 4-phenyl substituents. The phenyloxenium ion has much greater charge localization on the ring primarily at the para position.

4.3.4.2. Enium Ions of Other Group 16 Elements. Furukawa et al. have obtained enium ions of the heavier chalcogen elements stabilized by intramolecular complexation with dimethylamino groups. Resonances of the benzylic and methyl protons in the ¹H NMR spectrum of cation are shifted downfield.
indicative of the coordination of nitrogen to sulfur. There is no cation–anion contact in the solid state. The S–N distances are longer than the covalent single bond (2.063 versus 1.74 Å) and the molecular structure reveals a significant distortion of the N–S–N angle from linearity (168.54°). The charge on the sulfur atom was calculated to be +0.550 with the two nitrogen atoms negatively charged (−0.535). Bond orders were found to be 0.379 (Mulliken) and 0.539 (Löwdin). The singlet peak in the 77Se NMR spectrum of cation 322b is significantly deshielded relative to the neutral precursor (δ77Se 1208 and 90, respectively) and a similar phenomenon is observed in the 125Te NMR spectrum of cation 322c (δ125Te 1950 versus 287). These changes are characteristic of cationic species.

The 323 pentamesityltritellurium cation has been prepared and characterized. The two Mes2Te groups in the cation are NMR equivalent. Their signal (δ125Te +854) and that of the central MesTe unit (δ125Te +388) exhibit different broadening indicative of dynamic exchange equilibria. The Te3 unit is not linear (Te–Te–Te bond angle = 159.51°), and the Te–Te bonds are unsymmetric (2.979 and 3.049 Å) and significantly longer than the single bond in 108b. The valence shell of the central Te atom contains 10 electrons and, consequently, the Te3 unit is a nonclassical hypervalent moiety.

The energies and geometries of the phenylsulfenium cation have been optimized by ab initio calculations (MP2/6-31G*//MP2/6-31G* level) and the singlet state has been found to be 63.0 kcal mol−1 more stable than the triplet state.

4.4. HOMO- AND HETEROPOLYATOMIC CATIONS

In this section, the polyatomic cations of group 17 elements (halogen and interhalogen cations and polycations), cations and polycations of group 16 elements (O, S, Se, and
Te), and mixed polyheteroatom cations of group 15, 16, and 17 elements obtained in superacid media will be discussed.

### 4.4.1. Halogen Cations

The existence of many well-known compounds in which chlorine, bromine, and iodine are found in the +1 oxidation state led to the assumption that the cations Cl$^+$, Br$^+$, and I$^+$ are important and stable entities or at best as reaction intermediates. However, no evidence exists for monoatomic Cl$^+$, Br$^+$, and I$^+$ as stable species.\textsuperscript{771,772} In contrast, a whole series of polyatomic halogen cations are known.\textsuperscript{773–776}

#### 4.4.1.1. Iodine Cations

The existence of I$_3^+$ and I$_5^+$ ions, deduced by Masson\textsuperscript{777} 70 years ago in aromatic iodination reactions, has been confirmed now by physical measurements. The controversy over the nature of blue solutions of iodine in strong acid media has now been settled. It has been shown conclusively that these solutions contain I$_2^+$ ions\textsuperscript{778–780} and not I$^+$ as suggested earlier.\textsuperscript{781}

**I$_3^+$ and I$_5^+$ Ions.** The first evidence for stable iodine cations was obtained by Masson.\textsuperscript{777} He postulated the presence of I$_3^+$ (324) and I$_5^+$ (325) ions in solutions of iodine and iodic acid in sulfuric acid to explain the stoichiometry of the reaction of such solutions with chlorobenzene to form both iodo and iodoso derivatives. Later, Symons and co-workers\textsuperscript{782} gave conductometric evidence for I$_3^+$ formed from iodic acid and iodine in 100% sulfuric acid and suggested that I$_5^+$ may be formed on the basis of changes in the UV and visible spectra when iodine is added to I$_3^+$ solutions. Gillespie and co-workers,\textsuperscript{783} on the basis of detailed conductometric and cryoscopic measurements, confirmed that I$_3^+$ is formed from HIO$_3$ and I$_2$ in 100% sulfuric acid [Eq. (4.185)]. The I$_3^+$ cation may also be prepared in fluorosulfuric acid.\textsuperscript{778} Solutions of red brown I$_3^+$ 324 in H$_2$SO$_4$ or HSO$_3$F have characteristic absorption maxima at 303 and 470 nm, with a molar extinction coefficient of 5200 at 305 nm.

\[
\text{HIO}_3 + 7\text{I}_2 + 8\text{H}_2\text{SO}_4 \rightarrow 5\text{I}_3^+ + 3\text{H}_3\text{O}^+ + 8\text{HSO}_4^- \tag{4.185}\]

Solutions of I$_3^+$ in 100% sulfuric acid\textsuperscript{783} or fluorosulfuric acid\textsuperscript{778} dissolve at least 1 mol of iodine per mol of I$_3^+$, and a new absorption spectrum is obtained which has bands at 240, 270, 345, and 450 nm. At the same time, there is no change in either the conductivity or the freezing point of the solutions. This leads to the conclusion that ion I$_5^+$ 325 is formed [Eq. (4.186)]. Some further iodine also dissolves in solutions of I$_3^+$, indicating possible formation of I$_7^+$.

\[
\text{I}_3^+ + \text{I}_2 \rightarrow \text{I}_5^+ \tag{4.186}\]
Solutions of $\text{I}_3^+$ 324 in $\text{H}_2\text{SO}_4$ give Raman spectra $^784$ that have three bands, in addition to the solvent peaks at 114, 207, and 233 cm$^{-1}$ which may be assigned as the $v_2$, $v_1$, and $v_3$ vibrations of an angular molecule. The average stretching frequency of 220 cm$^{-1}$ in the $\text{I}_3^+$ molecule is appreciably lower than the stretching frequency of 238 cm$^{-1}$ for the $\text{I}_2^+$ molecule and, in fact, closer to the frequency of 213 cm$^{-1}$ for the neutral molecule $\text{I}_2$. This is consistent with $\text{I}_3^+$ having a formal $\text{I}^+-\text{I}$ bond order of 1.0 for both bonds as in the simple valence bond formation 324, whereas that in $\text{I}_2^+$ is 1.5.

![Diagram](image)

On the basis of $^{127}\text{I}$ nuclear quadrupole resonance (NQR) studies of $\text{I}_3^+\text{AlCl}_4^-$, Corbett and co-workers $^785$ have predicted a bond angle of 97$^\circ$ between the two bonding orbitals on the central atom. X-ray crystal structures of $\text{I}_3^+\text{AlCl}_4^-$ and $\text{I}_5^+\text{SbF}_6^-$ have been obtained $^{786,787}$. In the latter salt, two cations are weakly bound to a central $\text{I}_5^+$ ion and the moiety can be regarded as $\text{I}_{15}^+ (\text{SbF}_6^-)_3$. In contrast, in the salt $\text{I}_5^+\text{AsF}_6^-$ prepared subsequently by Passmore, White, and co-workers $^788$ by oxidizing iodine with AsF$_5$ in liquid SO$_2$, the cation $\text{I}_5^+$ (325) exists. It is planar, has $C_{2v}$ symmetry and a Z-shaped (trans) structure (325), and features the following characteristics: I(1)–I(2) and I(2)–I(3) bond lengths $= 2.645$ and 2.895 Å, respectively, I–I–I bond angles $= 97.0^\circ$ and 180$^\circ$.

![Diagram](image)

The bonding in $\text{I}_5^+$ (and in Br$_5^+$) can be described in terms of valence bond structures 325a and 325b showing a formal bond order of 1 for the terminal I–I bonds. $^788$ The bond order of the central bonds is 0.5, and these bonds may be considered as three-center four-electron bonds.

$I_2^+$ ion. Gillespie and Milne have shown, $^778$ by conductometric, spectrophotometric, and magnetic susceptibility measurements, that the blue iodine species observed in strong acids is $\text{I}_2^+$ 326. When iodine was oxidized by peroxodisulfuryl difluoride in fluorosulfuric acid [Eqs. (4.187) and (4.188)], the concentration of the blue iodine species reached a maximum at 2:1 $\text{I}_2:\text{S}_2\text{O}_8\text{F}_2$ mole ratio and not at the 1:1 mole ratio as would be anticipated for the formation of $\text{I}^+$. The conductivities of 2:1 solutions of iodine:$\text{S}_2\text{O}_8\text{F}_2$ at low concentrations were found to be very similar to solutions of KSO$_3$F at the same concentration, showing that 1 mol of FSO$_3^-$ had been formed per mole of iodine. The magnetic moment of the blue species in fluorosulfuric acid was found to be $2.0 \pm 0.1$ D, which agreed with the value expected for the $^3\pi_{3/2}$ ground state of the $\text{I}_2^+$ cation 326. The $\text{I}_2^+$ has characteristic peaks in its UV absorption spectrum at
640, 490, and 410 nm and has a molar extinction coefficient of 2560 at 640 nm.

\[
2I_2 + S_2O_6F_2 \rightarrow 2I_2^+ + 2FSO_3^- \quad (4.187)
\]

\[
I_2 + S_2O_6F_2 \rightarrow 2I^+ + 2FSO_3^- \quad (4.188)
\]

The \( I_2^+ \) cation is not completely stable in fluorosulfuric acid and undergoes some disproportionation to the more stable \( I_3^+ \) ion \( 324 \) and \( I(SO_3F)_3 \) [Eq. (4.189)]. This disproportionation is largely prevented in a 1:1 iodine:S\(_2\)O\(_6\)F\(_2\) solution in which \( I(SO_3F)_3 \) is also formed [Eq. (4.190)].

\[
8I_2^+ + 3FSO_3^- \leftrightarrow 5I_3^+ + I(SO_3F)_3 \quad (4.189)
\]

\[
5I_2 + 5S_2O_6F_2 \rightarrow 4I_2^+ + 4FSO_3^- + 2I(SO_3F)_3 \quad (4.190)
\]

The disproportionation can also be prevented if the fluorosulfate ion concentration in fluorosulfuric acid is lowered by addition of antimony pentafluoride [Eq. (4.191)] or by using the less basic solvent, 65% oleum.

\[
SbF_5 + FSO_3^- \rightarrow (SbF_5SO_3F)^- \quad (4.191)
\]

In 100% \( H_2SO_4 \), the disproportionation of \( I_2^+ \) to \( I_3^+ \) and an iodine(III) species, probably \( I(SO_4H)_3 \), is essentially complete, and only traces of \( I_2^+ \) can be detected by means of its resonance Raman spectrum.

Solution of the blue iodine cation in oleum has been reinvestigated\(^779\) by conductometric, spectrophotometric, and cryoscopic methods confirming the formation of \( I_2^+ \). In 65% oleum, iodine is oxidized to \( I_2^+ \) [Eq. (4.192)].

\[
2I_2 + 5SO_3 + H_2S_4O_{13} \rightarrow 2I_2^+ + 2HS_4O_{13}^- + SO_2 \quad (4.192)
\]

Adhami and Herlem\(^789\) have carried out a coulometric titration at controlled potential of iodine in fluorosulfuric acid and have shown that iodine is quantitatively oxidized to \( I_2^+ \) by removal of one electron per mole of iodine.

Pure crystalline \( I_2^+\)Sb\(_2\)F\(_{11}\) has been prepared by the reaction of iodine with antimony pentafluoride in liquid sulfur dioxide as solvent.\(^789\) After removal of insoluble \( SbF_3 \), deep blue crystals of \( I_2^+\)Sb\(_2\)F\(_{11}\) were obtained from the solution. An X-ray crystallographic structure determination showed the presence of the discrete
I$_2^+$ and Sb$_2$F$_{11}^-$ ions. Crystalline solids that can be formulated as I$_2^+$Sb$_2$F$_{11}^-$ have also been prepared by Kemmitt et al. by the reaction of iodine with antimony or tantalum pentafluoride in iodine pentafluoride solutions.

Besida and O'Donnell have studied the existence and stabilization of iodine cations in hydrogen fluoride using Lewis acids (NbF$_5$, TaF$_5$, SbF$_5$) and NaF to control acidity and basicity. Excess F$^-$ causes disproportionation of the cations I$_5^+$, I$_3^+$, and I$_2^+$ to I$_2$ and IF$_5$. When these products are dissolved in HF and the acidity level is adjusted appropriately, the individual cations can be generated.

$I_4^{2+}$ Dication. In an early study of the I$_2^+$ cation, Gillespie et al. observed that on cooling the HSO$_3$F solution the color of the solution changed from an intense blue to a deep red-brown at about $-80^\circ$C with the concomitant considerable decrease of the paramagnetism. This was suggested to result from the dimerization of the paramagnetic I$_2^+$ ion to the diamagnetic I$_4^{2+}$ cation. Subsequently, they were able to prepare the I$_4^{2+}$ dication by the reaction of iodine with either AsF$_5$ or SbF$_5$ solution [Eq. (4.193)].

$$2 \text{I}_2 + 4 \text{MF}_5 \xrightarrow{\text{SO}_2 \text{RT}} \text{I}_4^{2+} \text{Y}^-$$

$M = \text{As, Sb}$

The X-ray crystal structure of salts I$_4^{2+}$(AsF$_6$)$_2^-$ and I$_4^{2+}$(Sb$_3$F$_{14}^-$)SbF$_6^-$ have been determined. The I$_4^{2+}$ dication is described as two I$_2^+$ cations bonded together by two relatively weak bonds. The interaction between the two I$_2^+$ ions may be described as a four-center two-electron $\pi^*$$-\pi^*$ bond formed between the singly occupied antibonding $\pi^*$ molecular orbitals of the two I$_2^+$ monomers. Each of the long iodine–iodine bonds has a bond order of 0.5. This model is consistent with the long I–I distances and the diamagnetism of the dication.

### 4.4.1.2. Bromine Cations

**Br$_3^+$ Ion.** In 1906, Ruff et al. prepared a compound by the reaction of Br$_2$ and SbF$_5$, which was formulated as SbF$_5$Br. Later McRae showed that Br$_3^+$ is formed in the system. Subsequently, Gillespie and Morton found that Br$_3^+$ is formed quantitatively in the superacid medium HSO$_3$F–SbF$_5$–SO$_2$ (mainly be the reaction of S$_2$O$_6$F$_2$) [Eq. (4.194)].

$$3 \text{Br}_2 + \text{S}_2\text{O}_6\text{F}_2 \rightarrow 2 \text{Br}_3^+\text{FSO}_3^-$$

These solutions are brown in color and have a strong absorption at 300 nm with a shoulder at 375 nm. Solutions of Br$_3^+$ can also be obtained in a similar way in
fluorosulfuric acid; however, they are not completely stable in this solvent and undergo some disproportionation [Eq. (4.195)].

\[
\begin{align*}
\text{Br}_3^+ + \text{FSO}_3^- & \rightarrow \text{Br}_2 + \text{BrOSO}_2\text{F} \\
\text{Eq. (4.195)} & \\
\end{align*}
\]

Glemser and Šmalc\textsuperscript{798} have prepared the compound \(\text{Br}_3^+\text{AsF}_6^-\) by the displacement of oxygen in dioxygenyl hexafluoroarsenate by bromine [Eq. (4.196)] and by the reaction of bromine pentafluoride, bromine, and arsenic pentafluoride [Eq. (4.197)]. The compound is chocolate-brown and in solution has absorption bands at 310 nm and 375 nm; it has fair thermal stability and can be sublimed at 30–50°C under nitrogen atmosphere.

\[
\begin{align*}
2\text{O}_2^+\text{AsF}_6^- + 3\text{Br}_2 & \rightarrow 2\text{Br}_3^+\text{AsF}_6^- + 2\text{O}_2 \\
\text{Eq. (4.196)} & \\
7\text{Br}_2 + \text{BrF}_5 + 5\text{AsF}_5 & \rightarrow 5\text{Br}_3^+\text{AsF}_6^- \\
\text{Eq. (4.197)} & \\
\end{align*}
\]

Christe et al.\textsuperscript{799} have obtained the crystal structure of the \(\text{Br}_3^+\text{AsF}_6^-\) salt and showed that it contains discrete ions with some cation–anion interactions. The \(\text{Br}_3^+\) cation is symmetric with a bond distance of 2.270 Å and a bond angle of 102.5°.

**\(\text{Br}_2^+\) Ion.** The \(\text{Br}_2^+\) cation\textsuperscript{329} can be prepared\textsuperscript{797} by oxidation of bromine by \(\text{S}_2\text{O}_6\text{F}_2\) in the superacid \(\text{HSO}_3\text{F–SbF}_5–3\text{SO}_3\); however, even in this very weakly basic medium, the \(\text{Br}_2^+\) ion is not completely stable because it undergoes appreciable disproportionation [Eq. (4.198)].

\[
\begin{align*}
2\text{Br}_2^+ + 2\text{HSO}_3\text{F} & \leftrightarrow \text{Br}_3^+ + \text{BrOSO}_2\text{F} + \text{H}_2\text{SO}_3\text{F}^+ \\
\text{Eq. (4.198)} & \\
\end{align*}
\]

Moreover, the \(\text{BrOSO}_2\text{F}\) that is formed also undergoes some disproportionation by itself to \(\text{Br}_2^+, \text{Br}_3^+, \text{and Br(OSO}_2\text{F})_3\), [Eqs. (4.199) and (4.200)], and the equilibria in these solutions are quite complex.

\[
\begin{align*}
5\text{BrOSO}_2\text{F} + 2\text{H}_2\text{SO}_3\text{F}^+ & \leftrightarrow 2\text{Br}_2^+ + \text{Br(OSO}_2\text{F})_3 + 4\text{HSO}_3\text{F} \\
\text{Eq. (4.199)} & \\
4\text{BrOSO}_2\text{F} + \text{H}_2\text{SO}_3\text{F}^+ & \leftrightarrow \text{Br}_3^+ + \text{Br(OSO}_2\text{F})_3 + 2\text{HSO}_3\text{F} \\
\text{Eq. (4.200)} & \\
\end{align*}
\]

HOMO- AND HETEROPOLYATOMIC CATIONS 431
A solution of Br$_2^+$ [329] in superacid has a characteristic cherry red color with maximum absorption at 510 nm and a single band in the Raman spectrum at 360 cm$^{-1}$. The paramagnetic scarlet crystalline compound Br$_2^+${Sb,3F$_{16}^-$} has been prepared$^{800,801}$ according to Eq. (4.201).

$$
9\text{Br}_2 + 2\text{BrF}_5 + 30\text{SbF}_5 \rightarrow 10\text{Br}_2^+\text{SbF}_{16}^- \\
(4.201)
$$

It is a stable salt and can be sublimed at 200°C. The X-ray crystal structure of Br$_2^+${Sb,3F$_{16}^-$} [329] shows a bromine–bromine bond distance of 2.13 Å. The shorter bond distance of 329 compared to neutral bromine is in accord with increase in bond order resulting from the loss of an antibonding electron from the neutral molecule.$^{800,801}$

**Br$_5^+$ Ion.** The Br$_5^+$ cation was first isolated$^{799}$ as a mixture of Br$_3^+${As,6F$^-$} and Br$_5^+${As,6F$^-$}. On the basis of the Raman spectrum, it was shown to have three colinear central bromine atoms with a semi-ionic, three-center four-electron bond and two terminal, perpendicular bromine atoms with covalent bonds. Minkwitz and co-workers$^{802}$ have obtained the 330 salts by oxidation with XeF$^+$ [Eq. (4.202)]. The planar trans geometry of the cation is similar to that of I$_5^+$ (325). It is centrosymmetric in the solid state with two short bonds between the external bromine atoms (2.275 Å in the AsF$_6^-$ and 2.268 Å in the SbF$_6^-$ salt) and two longer bonds to the central atom (2.512 and 2.514 Å in the AsF$_6^-$ and SbF$_6^-$ salts, respectively). The Br(1)–Br(2)–Br(3) bond angles are 96.91 and 97.69°, respectively. According to local density functional calculations,$^{803}$ in the optimized structure the three central bromine atoms deviate from linearity by 11.4° and the terminal bromine atoms form a dihedral angle of 82° about the Br(2)–Br(4) axis.

$$
3\text{XeF}^+\text{M}^- + 8\text{Br}_2 \underset{RT}{\rightarrow} 3\text{Br}_5^+\text{M}^- + 3\text{Xe} + \text{BrF}_3 \\
M = \text{As, Sb} \\
(4.202)
$$

### 4.4.1.3. Chlorine Cations

**Cl$_3^+$ Ion.** There is no evidence for either Cl$^+$ or Cl$_2^+$ in superacid media.$^{804}$ However, Cl$_2$, ClF, and AsF$_5$ react at -70°C to form Cl$_3^+${As,6F$^-$} [Eq. (4.203)].$^{772}$

$$
\text{Cl}_2 + \text{ClF} + \text{AsF}_5 \rightarrow \text{Cl}_3^+\text{AsF}_{6}^- \\
(4.203)
$$

The Cl$_3^+$ cation 331 has been identified by its Raman spectrum in the yellow solid which precipitates from solution of Cl$_2$ and ClF in HF–SbF$_5$ at -76°C or formed by treating ClF$_2^+$AsF$_6^-$ with chlorine.$^{772}$ At room temperature the Cl$_3^+$ cation completely
disproportionates in the HF–SbF$_5$ media to chlorine and ClF$_2^+$ salts. There is no evidence for the formation of Cl$_3^+$BF$_4^-$ salt from mixtures of Cl$_2$, ClF, and BF$_3$ at temperatures ranging from ambient to $-120^\circ$C.

The Raman spectrum of Cl$_3^+$AsF$_6^-$ shows bands due to the AsF$_6^-$ ion, together with three relatively intense bands at 490 (split to 485 and 493), 225, and 508 cm$^{-1}$. These frequencies are very close to the vibrational frequencies of neutral SCl$_2$ molecule. Subsequently, Clegg and Downs isolated the bright-orange Cl$_3^+$SbF$_{11}^-$ salt at room temperature and Minkwitz et al. performed Raman characterization of Cl$_3^+$SbF$_6^-$. Seppelt and co-workers have synthesized Cl$_3^+$ salts by warming Cl$_2$O$_2^+$ salts to room temperature [Eq. (4.204)] and isolated yellow crystals. The Cl$_3^+$ cation in all salts exists as a symmetric, bent entity with Cl–Cl bond distances of 1.972–1.994 Å and bond angles of 104.51–105.62$^\circ$.

\[
\text{Cl}_2\text{O}_2^+M^- + \text{HF-SbF}_5 \xrightarrow{\text{RT, } 1 \text{ day}} \text{Cl}_3^+M^-
\]

A DZP calculation by Burdett and Marsden predicted a bent structure for Cl$_3^+$ (Cl–Cl bond length = 2.010, bond angle = 105.6$^\circ$). Calculations by Olah and co-workers found the Cl$_3^+$ ion a bent ground-state singlet (1.998 Å and 107$^\circ$) with a singlet–triplet gap of only 2.5 kcal mol$^{-1}$. Further ab initio calculations for all four X$_3^+$ ions were performed by Schwarz and co-workers (RHF and MP2 levels with different basis sets). Cacace et al. have prepared the Cl$_3^+$ ion in the gas phase and investigated with FT–ICR mass spectrometry and DFT method. The theoretical study [B3LYP/6-311++G(3df)] shows that the global minimum on the Cl$_3^+$ energy surface is a singlet of C$_2v$ symmetry with a Cl–Cl bond distance of 1.996 Å and a bond angle of 110.0$^\circ$.

Cl$_4^+$ Ion. In an attempt to generate the elusive Cl$_2^+$ cation, Seidel and Seppelt have oxidized chlorine with IrF$_6$. Instead, however, they isolated the blue salt Cl$_4^+$IrF$_6^-$. The compound contains a rectangular Cl$_4^+$ ion with one short (1.941 Å) and one long Cl–Cl bond (2.936 Å) and without any significant contact with fluorine atoms.

4.4.2. Interhalogen Cations

Interhalogen cations form a class of polycations containing at least two different halogen atoms. Cations containing one or more halogens and another element such as oxygen, nitrogen, or xenon will not be considered here. The class of interhalogen cations includes triatomic, pentaatomic, and heptaatomic systems. Many of these interhalogen cation salts, which are strong oxidants, have been found useful for collecting radioactive noble gases such as $^{222}$Rn and $^{133}$Xe.

4.4.2.1. Triatomic Interhalogen Cations. Of all the possible 16 triatomic interhalogen cations ClF$_2^+$, BrF$_2^+$, IF$_2^+$, Cl$_2$F$^+$, Br$_2$F$^+$, I$_2$F$^+$, ClBrF$^+$, ClIF$^+$, BrIF$^+$,
BrCl$_2^+$, ICl$_2^+$, Br$_2$Cl$^+$, I$_2$Cl$^+$, BrICl$^+$, IBr$_2^+$, and I$_2$Br$^+$, only five are known. They are ClF$_2^+$, BrF$_2^+$, IF$_2^+$, Cl$_2$F$^+$, and ICl$_2^+$. It seems reasonable to predict that the least electronegative halogen occupies the central position, where it carries a formal positive charge.

**ClF$_2^+$ ion.** Adducts of ClF$_3$ with Lewis acids such as AsF$_5$, SbF$_5$, and BF$_3$ have been known for some time, and it has been established by IR, Raman, and $^{19}$F NMR spectroscopic studies that these compounds are best formulated as salts of ClF$_2^+$ cation. The spectroscopic data indicate a bent structure. Additional support for the bent structure of ClF$_2^+$ comes from X-ray crystallographic studies on ClF$_2^+$ salts. The ClF$_2^+$ ion has a bond angle of 95.9° and a bond length of 1.58 Å. There is a good evidence for the fluorine bridging between the anion and the cation and the two fluorine bridges formed by each ClF$_2^+$ give rise to a very approximately square coordination of fluorine around chlorine, which is the geometry predicted by the valence shell electron-pair-repulsion theory for AX$_4$E$_2$ coordination (where X is a ligand and E a lone pair). It is interesting to note that the SbF$_6^-$ ion in this structure forms trans bridges rather than the cis bridges that have been observed in other related systems.

![Image](https://via.placeholder.com/150)

**BrF$_2^+$ ion.** The 1:1 adduct of BrF$_3$ with SbF$_5$ has been shown by X-ray crystallography to contain BrF$_2^+$ and SbF$_6^-$ ions held together by fluorine bridging in such a way that bromine acquires a very approximately square-planar configuration. Each bromine atom has two fluorine atoms at 1.69 Å, making an angle of 93.5° at bromine, and two other neighboring fluorine atoms at 2.29 Å which form part of the distorted octahedral coordination of the antimony atoms. The two fluorine bridges formed by SbF$_6^-$ are cis rather than trans, as in the unusual structure ClF$_2^+$SbF$_6^-$.

The IR and Raman spectra of BrF$_3$–SbF$_5$, BrF$_3$–AsF$_3$, and (BrF$_3$)$_2$GeF$_4$ have been reported. The electrical conductivity of liquid bromine trifluoride (specific conductance $= 8 \times 10^{-3}$ ohm$^{-1}$ cm$^{-1}$) may be attributed to self-ionization [Eq. (4.205)].

$$2 \text{BrF}_3 \rightleftharpoons \text{BrF}_2^+ \text{BrF}_4^- \quad (4.205)$$

**IF$_2^+$ ion.** The salts of IF$_2^+$ with AsF$_6^-$ and SbF$_6^-$ anions have been prepared from IF$_3$ and AsF$_5$, and from IF$_3$ and SbF$_5$ in AsF$_5$ as solvent at $-78^\circ$C. The compound IF$_2^+$SbF$_6^-$ is stable up to 45°C and the solid gives two broad overlapping $^{19}$F NMR
signals whose relative intensities were estimated to be 1:2.6 and which were assumed to arise, therefore, from fluorine on iodine and fluorine on antimony, respectively. IF$_2^+$AsF$_6^-$ was found to be stable only up to −20°C.

**ClF$_2^+$ Ion.** Raman spectra of the adducts AsF$_5$–2ClF and BF$_3$–2ClF have established that these compounds contain the unsymmetrical ClCIF$^+$ cation$^{805}$ and not the symmetrical ClFCl$^+$ cation previously reported on the basis of the IR spectrum alone.$^{826}$ The observed vibrational frequencies indicate that there is a strong fluorine bridging between the cation and the anion in ClF$_2^+$AsF$_6^-$ 333 salt. Theoretical calculations confirm that the ClCIF$^+$ cation is more stable by 43.0 kcal mol$^{-1}$ [MP4(SDTQ)/6-311G(2df)//M3/6-311G(2df) + ZPE level]$^{827}$ and 44.3 kcal mol$^{-1}$ [CCSD(T)/cc-pVQZ level].$^{813}$ Cl–F bond strength in the ClCIF$^+$ cation is twice as strong as in cation ClFCl$^+$ (41.6 kcal mol$^{-1}$ versus 21.2 kcal mol$^{-1}$).$^{827}$

The Cl$_2$F$_2^+$ ion 333 appears to be unstable in solution and was found to be completely disproportionated in HF–SbF$_5$ even at −78°C$^{805}$ [Eq. (4.206)]. As mentioned, Cl$_3^+$ in the media disproportionates further at room temperature to give chlorine and 332-Cl.

$$2 \text{ClF}_2^+ \leftrightarrow \text{ClIF}_2^+ + \text{Cl}_3^+ \quad (4.206)$$

**ICl$_2^+$ Ion.** X-ray crystallographic investigations$^{828}$ of the adducts of ICl$_3$ with SbF$_5$ and AlCl$_3$ have shown that these may be regarded as ionic compounds, that is, ICl$_2^+$SbCl$_6^-$ and ICl$_2^+$AlCl$_4^-$. However, there is considerable interaction between the two ions via two bridging chlorines, which give an approximately square-planar arrangement of four chlorines around the iodine atom, similar to the arrangement of fluorines around bromine and chlorine in BrF$_2^-$SbF$_6^-$ and ClF$_2^+$SbF$_6^-$, respectively. The bond angle and bond length for ICl$_2^+$ 334 were found to be 92.5° and 2.31 Å in ICl$_2^+$SbCl$_6^-$ and 96.7° and 2.28 Å in ICl$_2^+$AlCl$_4^-$. The electrical conductivity of ICl$_3$ (specific conductance $= 9.85 \times 10^{-2}$ ohm$^{-1}$ cm$^{-1}$) can be attributed to the self-ionization.$^{828}$

**I$_2$Cl$^+$ Ion.** There is no certain evidence for the I$_2$Cl$^+$ cation 335, but presumably the electrical conductivity of liquid ICl (specific conductance $= 4.60 \times 10^{-3}$ ohm$^{-1}$ cm$^{-1}$ at 35°C) which has previously been ascribed to the self-ionization$^{829}$ according to Eq. (4.207) is in fact due to a self-ionization that produces I$_2$Cl$^+$ ion 335 [Eq. (4.208)].

$$2\text{Cl} \leftrightarrow \text{I}^+ + \text{ICl}_2^- \quad (4.207)$$

$$3\text{ICl} \leftrightarrow \text{I}_2\text{Cl}^+ + \text{ICl}_2^- \quad (4.208)$$

335
The I$_2$Cl$^+$ cation 335, however, is possibly extensively disproportionated to give the known I$_3^+$ cation 324 and ICl$_2^+$ cation 334 [Eq. (4.209)].

$$2\text{I}_2\text{Cl}^+ \rightleftharpoons \text{I}_3^+ + \text{ICl}_2^+$$  \hspace{1cm} (4.209)

### 4.4.2.2. Pentaatomic Interhalogen Cations.

Chlorine pentafluoride forms 1:1 adducts with AsF$_5$ and SbF$_5$. The interpretation of Raman spectra of these adducts indicates the formation of ClF$_4^+$ cation.\textsuperscript{830} The $^{19}$F NMR spectrum of ClF$_4^+$ (a doublet with equal intensity) suggests two pairs of nonequivalent fluorine ligands and a structure of $C_{2v}$ symmetry.\textsuperscript{818} Bromine pentafluoride forms the adducts BrF$_5$–2SbF$_5$ and BrF$_5$–SO$_3$.\textsuperscript{831} These may, presumably be formulated as BrF$_4^+$ ion salts, although the latter compound might be the covalent BrF$_4$SO$_3$F. Iodine pentafluoride also forms adducts with SbF$_5$\textsuperscript{832} and PtF$_5$.\textsuperscript{833} The electrical conductivity of liquid IF$_5$ (specific conductance $= 2.30 \times 10^{-5}$ ohm$^{-1}$ cm$^{-1}$) has been attributed to the self-ionization [Eq. (4.210)]. In the Raman spectrum of IF$_4^+$, the observed nine lines have been assigned to cation IF$_4^+$ 336,\textsuperscript{834} which is consistent with its $C_{2v}$ structure found by X-ray crystallography.

$$2\text{IF}_5 \rightleftharpoons \text{IF}_4^+\text{IF}_6^-$$  \hspace{1cm} (4.210)

The X-ray crystal structure of the ClF$_4^+$SbF$_6^-$, BrF$_4^+$Sb$_2$F$_{11}^-$, and IF$_4^+$Sb$_2$F$_{11}^-$ salts have been obtained.\textsuperscript{835–837} All three salts contain discrete ions with the cation having pseudotrigonal bipyramidal structure like SF$_4$ with two fluorines occupying the axial positions and two fluorines and a lone pair occupying the equatorial positions (337). The axial X–F bonds are longer and of more ionic character (mean bond distances for ClF$_4^+$, BrF$_4^+$, and IF$_4^+$ are 1.618, 1.81, and 1.84 Å, respectively), whereas the equatorial bonds are shorter and more covalent (1.53, 1.77, and 1.77 Å). Each X atom forms two fluorine bridges with two different anions, resulting in pseudo-octahedral coordination of the central X atom and the formation of infinite zigzag chains. The minimum-energy structure of the cation ClF$_4^+$ was calculated to be of $C_{2v}$ symmetry at all levels of theory.\textsuperscript{837–840} Because of discrepancies between the observed and calculated values, Christe and co-workers\textsuperscript{841} have redetermined the structure of BrF$_4^+$Sb$_2$F$_{11}^-$ and IF$_4^+$Y$^-$ (Y = SbF$_6$, Sb$_2$F$_{11}$).
4.4.2.3. Heptaatomic Interhalogen Cations

**ClF₆⁺ Ion.** The PtF₆⁻ salt of cation ClF₆⁺ (338) has been prepared by the reaction of PtF₆ with chlorine fluorides [Eq. (4.211)] or oxyfluorides [Eq. (4.212)].

\[
\begin{align*}
2\text{ClF}_5^- + 2\text{PtF}_6^- &\xrightarrow{\text{sapphire reactor, RT, 8 days}} \text{ClF}_6^+\text{PtF}_6^- + \text{ClF}_4^+\text{PtF}_6^- \\
6\text{ClO}_2^- + 6\text{PtF}_6^- &\xrightarrow{-78^\circ C} \text{ClF}_6^+\text{PtF}_6^- + 5\text{ClO}_2^+\text{PtF}_6^- + \text{CO}_2
\end{align*}
\]  

(4.211)

(4.212)

Christe and co-workers have recently developed a new synthesis applying the highly reactive and thermally unstable NiF₃⁺ cation [Eq. (4.213)].

\[
\begin{align*}
\text{Cs}_2\text{NiF}_6^- + 5\text{AsF}_5^- + \text{XF}_5^- &\xrightarrow{\text{HF, -60 to 10^\circ C}} \text{XF}_6^+\text{AsF}_6^- + \text{Ni(AsF}_6)_2^- + 2\text{CsAsF}_6 \\
X &= \text{Cl, Br}
\end{align*}
\]  

(4.213)

The structure of ClF₆⁺ cation 338 has been established beyond any reasonable doubt by¹⁹F NMR spectroscopy. The ClF₆⁺ cation 338, except for the ClO₂F₂⁻ cation,⁸⁴⁵ is the only known heptacoordinate chlorine cation. Besides the well-known NF₄⁺ cation,⁸⁴⁶,⁸⁴⁷ it is the only known example of a fluorocation derived from the hitherto unknown compounds (i.e., NF₅ and ClF₇). Complete vibrational analysis of ClF₆⁺ cation 338 has been reported,⁸⁴⁸ and it indicates the octahedral symmetry of the ion.

The ClF₆⁺PtF₆⁻ salt is canary yellow in color and is quite stable at 25°C when stored in Teflon-FEP containers. The ClF₆⁺ salts are very powerful oxidizers and react explosively with organic compounds and water.

**BrF₆⁺ Ion.** In 1974 Gillespie and Schrobilgen reported the direct oxidation of bromine pentafluoride to BrF₆⁺ cation 339 by Kr₂F₃⁺ cation⁸⁴⁹,⁸⁵⁰ [Eq. (4.214)].

\[
\begin{align*}
\text{BrF}_5^- + \text{Kr}_2\text{F}_3^+\text{MF}_6^- &\xrightarrow{0^\circ C} \text{BrF}_6^+\text{MF}_6^- + \text{KrF}_2 + \text{Kr} \\
\text{M} &= \text{As, Sb}
\end{align*}
\]  

(4.214)

The ¹⁹F NMR and Raman spectroscopic studies on BrF₆⁺ 339 indicate the octahedral symmetry of the species. The ion 339 is a powerful oxidizing agent and rapidly oxidizes oxygen and xenon to O₂⁺ and XeF⁺ cations, respectively, under ambient conditions.

**IF₆⁺ Ion.** Iodine heptafluoride has been shown to form the adduct IF₇AsF₅ and IF₇⁻SbF₅.⁸⁵² The latter complex was postulated to have the ionic structure IF₄⁺(SbF₆⁻)₃. These findings were questioned by Christe and Sawodny,⁸⁵³ who indicated that the adduct may contain IF₆⁺ cation. Indeed they showed that the IF₇AsF₅ adduct is
actually the IF$_6^+$AsF$_6^-$ salt. Hohorst, Stein, and Gebert have been successful in preparing the IF$_6^+$SbF$_6^-$ salt.$^\text{854}$ The Raman and IR spectral analyses of the salts indicate the octahedral nature of the IF$_6^+$ cation.$^\text{854,855}$ The IF$_6^+$SbF$_6^-$ salt rapidly reacts with radon gas at room temperature forming a nonvolatile radon compound. The salt is claimed to have potential application in purifying radon-contaminated air and in the analysis of radon in air.$^\text{854}$

Schrobilgen, Christe, and co-workers have recently carried out the first detailed structural characterization of the XF$_6^+$ cations (X = Cl, Br, I) as their Sb$_2$F$_{11}^-$ salts.$^\text{856}$ The XF$_6^+$ cations have octahedral geometries with average bond lengths of 1.550 Å (Cl–F), 1.666 Å (Br–F), and 1.779 Å (I–F) measured at $-130^\circ$C and $-173^\circ$C. The cations have 13–16 interionic F–F contacts to the neighboring anions and six F–X contacts between the fluorine atoms of the anions and the central halogen atoms. Additional studies (NMR characterization of the central X atoms, Raman spectroscopy, and calculations) were also performed.

### 4.4.3. Polyatomic Cations of Group 16 Elements

#### 4.4.3.1. The O$_2^+$ Cation

The existence of O$_2^+$ cation$^\text{340}$ in the gas phase at low pressures has been well established.$^\text{772,857}$ However, it was not until 1962 that a compound containing O$_2^+$ was identified.$^\text{858}$ It was discovered as a reaction product during the fluorination of platinum in a silica apparatus. The product was first thought to be PtOF$_4$, but later it was shown to be O$_2^+$PtF$_6^-$. It was subsequently prepared by direct oxidation of molecular oxygen using platinum hexafluoride at room temperature. It now appears that the dioxygenyl salt O$_2^+$BF$_4^-$ may have been prepared prior to 1962.$^\text{860}$ There are at least nine O$_2^+$ salts known with a variety of anions. The anions are PtF$_6^-$, AsF$_6^-$, SbF$_6^-$, Sb$_2$F$_{11}^-$, PF$_6^-$, BF$_4^-$, VF$_6^-$, BiF$_6^-$, and SnF$_6^-$.

The most convenient route to O$_2^+$ salts appears to be the photochemical synthesis of O$_2^+$SbF$_{11}^-$ from oxygen, fluorine, and antimony pentafluoride.$^\text{861}$ Most O$_2^+$ preparations involve the reaction of fluoride ion acceptors with O$_2$F$_2$ or O$_4$F$_2$ at low temperatures or with O$_2$ and F$_2$ mixtures under conditions favoring synthesis of the long-lived radical O$_2$F [Eq. (4.215)].

$$
O_2 + F_2 \xrightarrow{\text{hv} \downarrow_{-F}} O_2F \xrightarrow{\text{SbF}_5} O_2^+\text{SbF}_{11}^- \quad (4.215)
$$

Compounds containing O$_2^+$ cation$^\text{340}$ are colorless with the exception of O$_2^+$PtF$_6^-$, which is red due to the PtF$_6^-$ ion. The compound O$_2^+$PF$_6^-$ decomposes slowly at $-80^\circ$C$^\text{862}$ and rapidly at room temperature, giving oxygen, fluorine, and phosphorous pentafluoride.$^\text{18}$F tracer studies on O$_2^+$BF$_4^-$ have led to the conclusion that the mechanism of the decomposition involves the equilibrium [Eq. (4.216)] followed by a bimolecular decomposition of O$_2$F.$^\text{863}$

$$
O_2^+\text{BF}_4^- \xrightarrow{} O_2F(g) + BF_3(g) \quad (4.216)
$$
Dioxygenyl hexafluoroantimonate has been studied by differential thermal analysis. Decomposition of $\text{O}_2^+\text{SbF}_6^-$ proceeds in two stages, according to the mechanism given in Eqs. (4.217) and (4.218).

$$2\text{O}_2^+\text{SbF}_6^- \xrightarrow{\sim-245^\circ C} \text{O}_2 + 0.5\text{F}_2 + \text{O}_2^+\text{Sb}_2\text{F}_{11}^- \quad (4.217)$$

$$\text{O}_2^+\text{Sb}_2\text{F}_{11}^- \xrightarrow{\sim-280^\circ C} \text{O}_2 + 0.5\text{F}_2 + 2\text{SbF}_5 \quad (4.218)$$

The $\text{O}_2^+\text{Sb}_2\text{F}_{11}^-$ was converted to $\text{O}_2^+\text{SbF}_6^-$ by heating at 130–180°C in vacuo; conversely, $\text{O}_2^+\text{Sb}_2\text{F}_{11}^-$ was prepared by reaction of $\text{O}_2^+\text{SbF}_6^-$ and SbF$_5$ at 180–200°C. Dioxygenyl hexafluorarsenate is markedly less stable than the hexafluoroantimonate salts; it decomposes rapidly at 130–180°C. $\text{O}_2^+\text{PtF}_6^-$ can be sublimed above 90°C in vacuo and melts with some decomposition at 219°C in a sealed tube.

X-ray powder data obtained from the cubic form of $\text{O}_2^+\text{PtF}_6^-$ were consistent with the presence of $\text{O}_2^+$ and PtF$_6^-$ ions. The structure was refined using neutron diffraction powder data. The $\text{O}_2^+$ cation resembles nitrosonium ion.

Recently, the X-ray crystal structures of $\text{O}_2^+\text{MF}_6^-$ salts (M = Sb, Ru, Pt, Au) have been determined. For the $\text{O}_2^+$ cation in the $\text{O}_2^+\text{RuF}_6^-$ salt, an interatomic O–O bond distance of 1.125 Å was found at 127°C in agreement with the gas-phase value of 1.1227 Å. Values obtained for the O–O bond length in the $\text{O}_2^+\text{AuF}_6^-$ salt are 1.068 Å (–122°C) and 1.079 Å.

The $\text{O}_2^+\text{AsF}_6^-$ salt readily oxidizes molecular bromine to $\text{Br}_3^+$ ion. The $\text{O}_2^+\text{BF}_4^-$ salt also reacts with xenon. The major application of $\text{O}_2^+$ salts is as an oxidant for collecting $^{222}\text{Rn}$ in uranium mines, since it has negligible dissociation pressure at ambient temperature and releases oxygen as a gaseous product. Reactions of the salt with radon and components of diesel exhausts (CO, CO$_2$, CH$_4$, SO$_2$, NO, and NO$_2$) have therefore been studied in some detail.

### 4.4.3.2. Polysulfur Cations

The nature of colored solutions obtained by dissolving elemental sulfur in oleum remained a mystery for a long time, since their discovery by Bucholz in 1804. Red, yellow, and blue solutions have been prepared; however, it appears that particular attention has been given to the blue solutions. The species responsible for blue color has been identified by various workers as $\text{S}_2\text{O}_3$, $\text{S}_2$, radical ion ($\text{X}_2\text{S–SX}_2^+$), and the species designated as $\text{S}_n$. The various colors have now been shown to be due to cations $\text{S}_{16}^{2+}$, $\text{S}_8^{2+}$, and $\text{S}_4^{2+}$. Subsequently, it was shown by X-ray crystallography that the originally assigned $\text{S}_{16}^{2+}$ cation is indeed $\text{S}_{19}^{2+}$.

Sulfur (and selenium) can be oxidized by a variety of oxidizing agents including AsF$_5$, SbF$_5$, and $\text{S}_2\text{O}_3\text{F}_2$ and by protic acids such as $\text{H}_2\text{S}_2\text{O}_7$ and $\text{HSO}_3\text{F}$. It has been shown that a trace amount of halogen facilitates the formation of $\text{S}_4^{2+}$ and $\text{Se}_4^{2+}$ dications. Along with previously mentioned doubly charged species, several singly...
charged radical cations have been claimed, of which only $S^5^{+}$ has been positively identified.\textsuperscript{883} So far these singly charged species have been observed only in solution. They do not appear to be as stable as the doubly charged species and hence are not well-characterized. In contrast, all the dipositive ions have been obtained in the form of relatively stable salts such as $S_4^{2+}$ (FSO$_3^-$)$_2$ and $S_8^{2+}$ (AsF$_6^-$)$_2$.\textsuperscript{878} The vibrational spectra of the $S_4^{2+}$ (MF$_6^-$)$_2$ (M = As, Sb) salts solvated by SO$_2$ have been reported.\textsuperscript{884}

In the case of $S_8^{2+}$ (AsF$_6^-$)$_2$ a single-crystal X-ray crystallographic analysis showed unequivocally that this cation has an exo–endo cyclic structure with a long transannular bond (341).\textsuperscript{880} Recently, the crystal structure of $S_8^{2+}$ (AsF$_6^-$)$_2$ has been redetermined.\textsuperscript{885} The $S_8^{2+}$ dication consists of a folded eight-membered ring of approximate $C_s$ symmetry. These findings are similar to those reported in the original study\textsuperscript{880} and reported for the $S_8^{2+}$ (SbF$_6^-$) (Sb$_2$F$_5^+$) (SbF$_6^-$)$_5$ salt.\textsuperscript{886} The average S–S single bond length in the cation is 2.051 Å and all sulfur atoms exhibit at least one S–F contact. The unusually long transannular bonds of 2.8–2.9 Å [S(2)–S(8), S(3)–S(7), S(4)–S(6)] were reproduced computationally [B3PW91 level of theory with 6-311G* and 6-311G(2df) basis sets].

The question of the blue color has recently been raised again by Passmore and Krossing.\textsuperscript{887} In fact, the blue color was assigned by Gillespie and Passmore to $S_8^{2+}$,\textsuperscript{888} but $S_8^{2+}$ (AsF$_6^-$)$_2$ has been shown to be red\textsuperscript{885}; that is, the blue color was not due to $S_8^{2+}$. However, the $S_8^{2+}$ (AsF$_6^-$)$_2$ salt, when dissolved in HSO$_3$F or SO$_2$, gives a blue solution, which contains the $S_5^{+}$ cation and an unknown component. A comparison of calculated and experimental UV–vis spectra indicates that the unknown species is the $S_6^{2+}$ dication, which is a 10π-electron Hückel system, and the blue color is likely due to the HOMO–LUMO π*-π* transition.\textsuperscript{887} The transition into the first excited state was calculated to be at 564 nm (CIS) and 555 nm (TD-DFT). The experimentally found maximum in the UV–vis spectra is at 585 nm.

By comparison with analogous selenium and tellurium ions,\textsuperscript{889,890} the $S_4^{2+}$ ion is proposed to have a square-planar structure. Additional support comes from infrared spectra,\textsuperscript{891} Raman and electronic spectra,\textsuperscript{891,892} magnetic circular dichroism,\textsuperscript{893} and molecular orbital calculations.\textsuperscript{894} Indeed, the X-ray analysis of $S_4^{2+}$ (AsF$_6^-$)$_2$, which crystallizes with at least 0.62 SO$_2$, shows that the cation is square-planar (S–S bond distance = 2.014 Å, bond angle = 90°).\textsuperscript{895} The corresponding values for the $S_4^{2+}$ (Sb$_2$F$_4$)$_2$ (Sb$_2$F$_5^+$) (SbF$_6^-$)$_5$ salt are 1.988 Å and 90°.\textsuperscript{886} According to recent observations,\textsuperscript{896} the crystal structure of the salt $S_4^{2+}$ (AsF$_6^-$)$_2$ AsF$_3$ consists of discrete square-planar $S_4^{2+}$ cations, octahedral AsF$_6^-$, and AsF$_3$ molecules, weakly linked by cation–fluorine interactions. The average S–S bond distance (1.964 Å) and angle (90°) are not significantly different from those observed for other salts.

\begin{center}
\includegraphics[width=0.5\textwidth]{341.png}
\end{center}
Calculations showed that the $S_4^{2+}$ cation is lattice-stabilized in the solid state, as compared to the $S_2^{+}$ cation, and presently available anions are unlikely to stabilize $S_2^{+}$ (and $Se_2^{+}$ and $Te_2^{+}$) in the solid phase.\textsuperscript{896,897}

Early evidence for the dipositive ion $S_{16}^{2+}$ was not so conclusive. The existence of cation $S_{16}^{2+}$ was first reported as a result of isolation of a red solid from the reaction of sulfur and $AsF_5$ in anhydrous HF solution.\textsuperscript{888} From the analytical data, the solid appeared to have a composition corresponding to $S_{16}(AsF_6)_2$. In a study of the progressive oxidation of sulfur by $S_2O_6F_2$ in $HSO_3F$, it was observed that some unreacted sulfur always remained until sufficient oxidant had been added to give a ratio of sulfur to $S_2O_6F_2$ of 16:1. The cryoscopic measurements were also consistent with the formulation of this ion as $S_{16}^{2+}$.\textsuperscript{878} However, attempts to obtain a single crystal of the ion from various acid solutions were unsuccessful. Subsequently, Gillespie and co-workers\textsuperscript{881} obtained both needle- and plate-like crystals originally believed to be $S_{16}^{2+}(AsF_6^-)_2$ in 2:1 mixture of $SO_2$ and $SO_2ClF$ at $-25^\circ C$. An X-ray crystallographic study of these crystals led to the surprising and the unexpected result that the compound had the composition $S_{19}^{2+}(AsF_6^-)_2$,—that is, that it is a salt of $S_{19}^{+}$ rather than $S_{16}^{+}$.

The structure of $S_{19}^{2+}(AsF_6^-)_2$ contains discrete $AsF_6^-$ anions and $S_{19}^{+}$ cations, the latter consisting of two seven-membered rings joined by a five-atom chain (342). In contrast to $S_{19}^{2+}(AsF_6^-)_2$, the two rings in $S_{19}^{2+}(SbF_6^-)_2$ have similar chair conformations.\textsuperscript{886} In both systems, there is a very noticeable short–long bond alternation. Furthermore, two of the $S$–$S$ bonds are significantly elongated [$S(1)–S(7) = 2.203$ \(\text{Å} \), $S(13)–S(14) = 2.202$ \(\text{Å} \)] since bonding and lone pairs of electrons on these atoms are virtually eclipsed.

Further information of the chemistry of polysulfur, polyselenium, and polytellurium cations can be found in reviews.\textsuperscript{773,776,876,898,899}

4.4.3.3. Polyselenium Cations. The colored solutions produced by dissolving elemental selenium in sulfuric acid were first observed by Magnus in 1827.\textsuperscript{900} Since then a number of workers have investigated the nature of selenium solutions in sulfuric acid, oleum, and sulfur trioxide, providing a substantial amount of data\textsuperscript{901} but with little understanding of the system. Subsequently, it was shown that these solutions contain the yellow $Se_4^{2+}$ and green $Se_8^{2+}$ polyatomic cations.\textsuperscript{902,903}
Polyselenium cations are less electrophilic than their sulfur analogs and give stable solutions in various strong acids. In fluorosulfuric acid, selenium can be oxidized quantitatively by $\text{S}_2\text{O}_6\text{F}_2$ to give yellow $\text{Se}_4^{2+}$ \textbf{343} [Eq. (4.219)].

\[
4\text{Se} + \text{S}_2\text{O}_6\text{F}_2 \xrightarrow{\text{HSO}_3\text{F}} \text{Se}_4^{2+} + 2\text{FSO}_3^- \quad (4.219)
\]

The addition of selenium to the yellow solution up to a 8:1 ratio of Se:$\text{S}_2\text{O}_6\text{F}_2$ did not appreciably affect the conductivity. This indicated that the FSO$_3^-$ ion concentration remained unchanged and that the Se$_4^{2+}$ ion is reduced by selenium to Se$_8^{2+}$ \textbf{344} [Eq. (4.220)].

\[
\text{Se}_4^{2+} + 4\text{SeS} \rightarrow \text{e}_g^{2+} \quad (4.220)
\]

Conductivity measurements of selenium in pure fluorosulfuric acid were also consistent with the formation of Se$_8^{2+}$ \textbf{344}.

Solutions of Se$_8^{+}$ in 100% H$_2$SO$_4$ may be prepared by heating selenium in the acid at 50–60°C; the element is oxidized by sulfuric acid [Eq. (4.221)]. The Se$_4^{2+}$ \textbf{343} can also be oxidized to Se$_8^{2+}$ \textbf{344} by selenium dioxide.

\[
8\text{Se} + 5\text{H}_2\text{SO}_4 \rightarrow \text{Se}_8^{2+} + 2\text{H}_3\text{O}^+ + 4\text{HSO}_4^- + \text{SO}_2 \quad (4.221)
\]

Various compounds containing cations Se$_4^{2+}$ and Se$_8^{2+}$ have been prepared by oxidizing selenium with SeCl$_4$, in the presence of acids (AlCl$_3$, SO$_3$, oleum, SbF$_5$, or AsF$_5$) or reacting Se with AsF$_5$ or SbF$_5$. All polyatomic selenium cations are diamagnetic, and so far no evidence has been reported for radicals analogous to S$_5^{+}$.

The crystal structure of $\text{Se}_4(\text{HS}_2\text{O}_7)_2$ has shown $\text{Se}_4^{2+}$ \textbf{343} to be square planar with an Se–Se bond distance of 2.283 Å. The average bond length in Se$_4^{2+}$ (Sb$_2$F$_4^{2-}$) (Sb$_2$F$_5^{-}$)(SbF$_6^{-}$)$_5$ is slightly smaller (2.260 Å), whereas in Se$_4^{2+}$ (AlCl$_4^{-}$)$_2$ it is practically identical (2.285 Å). These values are significantly less than that of 2.34 Å found in the Se$_8$ molecule, indicating some degree of multiple bonding. Such a result is consistent with a valence bond description of the molecule involving four-membered ring structures of the type \textbf{343a}. Alternatively, the structure can be understood in terms of molecular orbital theory. The circle in structure \textbf{343b} denotes a closed-shell (aromatic) 6π-electron system. Of the four π molecular orbitals, the two almost nonbonding ($e_g$) orbitals and the lower-energy ($b_{2u}$) bonding orbital are occupied by the six π electrons, leaving the upper antibonding ($a_{1g}$) orbitals empty. The intense yellow-orange color of Se$_4^{2+}$ has been attributed to the dipole-allowed excitation of an electron from an $e_g$ orbital to the lowest empty π orbital ($b_{2u}$).

Stephens has shown that the magnetic circular dichroism results are consistent with such a model. The structure is also consistent with a vibrational spectroscopic study and molecular orbital calculations.
The structure of Se$_8^{2^+}$ 344 in Se$_8$(AlCl$_4$)$_2$ is similar to that of S$_8^{2^+}$ (see also structure 341) except that the cross-ring distance Se(3)–Se(7) is relatively shorter (2.84 Å) than that found in the sulfur cation (2.859 Å). However, the distance in cation S$_8^{2^+}$ in the mixed (Te$_6^{4^+}$(Se$_8^{2^+}$)(AsF$_6^-$)$_6$(SO$_2$)$_2$) system is 2.905 Å. The cross-ring distances Se(4)–Se(6) and Se(2)–Se(8), are relatively long (3.29 and 3.35 Å) compared to those in S$_8^{2^+}$. All bond angles in Se$_8^{2^+}$ are more acute than those in S$_8^{2^+}$. The cation Se$_8^{2^+}$ is, therefore, reasonably well-described by valence bond structure 344'. In contrast to the S$_8^{2^+}$ cation, calculations could not reproduce the transannular bonds of the Se$_8^{2^+}$ cation.

The Se$_{10}^{2^+}$ cation 345 has also been prepared and characterized. The salts include Se$_{10}^{2^+}$(AsF$_6^-$)$_2$, Se$_{10}^{2^+}$(AlCl$_4^-$)$_2$, Se$_{10}^{2^+}$(SbF$_6^-$)$_2$, and Se$_{10}^{2^+}$(FSO$_3^-$)$_2$. The X-ray crystal structure of Se$_{10}^{2^+}$(SbF$_6^-$)$_2$ indicates that the Se$_{10}^{2^+}$ cation can be described as a six-membered boat-shaped ring linked across the middle by a chain of four selenium atoms; that is, it has a bicyclo[4.2.2]decane-type structure (345). The selenium–selenium bonds in the cation vary greatly in length from 2.24 to 2.44 Å. According to a $^{77}$Se NMR study, the Se$_{10}^{2^+}$ cation undergoes structural isomerization in SO$_2$ at ambient temperature. One of the isomers disproportionates below 273 K to give Se$_8^{2^+}$ and a higher nuclearity species, which was identified as Se$_{17}^{2^+}$ or, less likely, Se$_{18}^{2^+}$. The Se$_{17}^{2^+}$(NbCl$_6^-$)$_2$ and Se$_{17}^{2^+}$(TaBr$_6^-$)$_2$ salts have recently been isolated. The cation Se$_{17}^{2^+}$ consists of two seven-membered rings connected by a Se$_3$ chain; that is, it contains two three-coordinate Se atoms, which formally carry the positive charge.
4.4.3.4. Polytellurium Cations. The red color produced when tellurium dissolves in concentrated sulfuric acid was first observed as long ago as 1798, but the origin of this color for long remained a mystery. Subsequently, Bjerrum and Smith have studied the reaction of tellurium chloride with tellurium in molten AlCl$_3$–NaCl. They obtained a purple melt that they concluded contained the species Te$_{2n}^{2+}$, probably Te$_4^{2+}$, formed by the reaction shown in Eq. (4.222).

\[
\begin{align*}
7\text{Te} + \text{Te}^{4+} & \rightarrow 2\text{Te}_4^{2+} \\
\text{(4.222)}
\end{align*}
\]

About the same time, solutions of tellurium in various acids were investigated in detail. It was found that the red solutions are produced when tellurium is dissolved in sulfuric acid, fluorosulfuric acid, or oleum with the simultaneous production of SO$_2$, indicating that tellurium is oxidized. The electronic spectra of the solutions were found to be identical with those obtained by Bjerrum and Smith from their melts. Conductometric and cryoscopic measurements of the acid solutions led to the conclusion that they contain a species Te$_{2n}^{2+}$, which was certainly not Te$_2^{2+}$ but probably Te$_4^{2+}$. The formulation of the red species as Te$_4^{2+}$ was confirmed by the determination of the crystal structures of the chloroaluminate salts. In both cases, the Te$_4^{2+}$ ion lies on a center of symmetry and is almost exactly square planar. The average tellurium–tellurium distances of 2.661–2.673 Å are significantly shorter than the tellurium–tellurium distance of 2.864 Å within the spiral chain in elemental tellurium. This is consistent with a structure exactly analogous to that for Se$_4^{2+}$ in which each bond has 25% double-bond character. The Raman spectra of Te$_4^{2+}$ in solution and the solid state are analogous to those of Se$_4^{2+}$ and S$_4^{2+}$ but shifted to lower frequency. The magnetic circular dichroism and visible and UV spectrum of solutions of Te$_4^{2+}$ are also similar to those of Se$_4^{2+}$, as expected on the basis of their structural similarity and a molecular orbital study. Thermochemical measurements have shown that Te$_4^{2+}$ in Te$_4^{2+}$ (AsF$_6^–$)$_2$, but not Se$_4^{2+}$ in Se$_4^{2+}$ (AsF$_6^–$)$_2$, is lattice-stabilized in the solid state. The Te$_4^{2+}$ cation in Te$_4^{2+}$ (SbF$_6^–$)$_2$ has bond lengths slightly longer (2.669 and 2.676 Å) than those in the chloroaluminate salts. The cation is significantly distorted and has $D_{2h}$ symmetry compared with the expected $D_{4h}$ symmetry.

If the acid solutions of tellurium described earlier are warmed or if the oleum is sufficiently strong, then the color of the solutions changes from red to orange-yellow. The same change may also be produced by addition of an oxidizing agent such as peroxydisulfate to the sulfuric acid solutions or S$_2$O$_6^2$F$_2$ to the HSO$_3$F solutions. Absorption spectra and conductometric, cryoscopic, and magnetic measurements on the solutions in HSO$_3$F suggested that the yellow species was tellurium in +1
oxidation state and it was formulated as “$Te_n^{n+}$” where $n$ is even as the cation was found to be diamagnetic. Furthermore, these studies also established that “$Te_n^{n+}$” could not be $Te_2^{2+}$ and is probably $Te_4^{4+}$, although higher-molecular-weight species such as $Te_6^{6+}$ and $Te_8^{8+}$ could not be ruled out. On the contrary, Bjerrum\textsuperscript{926} concluded, from spectrophotometric measurements on solutions formed by the reduction of $TeCl_4$ with tellurium metal in KAlCl\textsubscript{4} melts buffered with KCl–ZnCl\textsubscript{2}, that the species was $Te_2^{2+}$. Subsequently, Gillespie and co-workers\textsuperscript{927,928} were able to show that the $Te_n^{n+}$ species is indeed a cluster cation $Te_6^{4+}$. The single-crystal X-ray crystallographic study on $Te_6(AsF_6)_4–2AsF_3$ and $Te_6(AsF_6)_4–2 SO_2$ indicate that the $Te_6^{4+}$ cation has a trigonal prismatic arrangement \ref{347}. In the $(Te_6^{4+})(Se_8^{2+})(AsF_6^-)_{6}(SO_2)$ system containing two different homopolyatomic cations the $Te_6^{4+}$ cation has the same prismatic structure.\textsuperscript{911}

Beck\textsuperscript{929} prepared a polymeric $Te_7WOBr_5$ material, and subsequently the $Te_7^{2+}(AsF_6^-)_2$ polymeric product was isolated by Kolis and coworkers.\textsuperscript{930} The infinite chains of the $Te_7^{2+}$ polycation in $Te_7^{2+}(AsF_6^-)_2$ consist of six-membered rings of chair conformation connected through Te atoms bridging between the Te(1) and Te(4) atoms \ref{348}. The shortest bond distance (2.688 Å) is between Te(2) and Te(3), whereas the longest one is the Te(4’)–Te(1) distance (2.859 Å). There is also a long contact between Te(4’) and Te(3) (3.221 Å), which is much less than the sum of the van der Waals radii (4.40 Å).

\subsection*{4.4.3.5. Polyheteroatom Cations} So far, only studies on homopolyatomic cations of oxygen, sulfur, selenium, and tellurium have been discussed. Most of them were of the type $X_n^{2+}$. There is a new class of polyatomic cations that comprise two or more heteroatoms.
When powdered tellurium metal (0.002 mol) was allowed to react with Se$_8^{2+}$(AsF$_6^-$)$_2$ (0.001 mol) in SO$_2$ at $-78\,^\circ$C and the mixture was allowed to warm up to room temperature under stirring, the dark green color of Se$_8^{2+}$ slowly diminished (over a 12-h period) resulting in the formation of Te$_2$Se$_8$(AsF$_6$)$_2$SO$_2$-$\Delta$. The X-ray crystal structure of this product indicates that the adduct has Te$_2$Se$_8^{2+}$ cation with a bicyclo[4.2.2]decane-type structure similar to that of the Se$_{10}^{2+}$ cation (345). By changing the ratio of tellurium metal to Se$_8^{2+}$ 344, Gillespie and co-workers$^{931}$ have managed to prepare Te$_3.7$Se$_{6.3}^{2+}$(AsF$_6^-$)$_2$. The structure of Te$_3.7$Se$_{6.3}^{2+}$ is similar to that of Te$_2$Se$_8^{2+}$.

Preparation of adducts Te$_2$Se$_6^{2+}$(MF$_6^-$)$_2$ (M = As, Sb), Te$_4.5$Se$_{5.5}^{2+}$(AsF$_6^-$)$_2$, and (Te$_2$Se$_6^{2+}$(Te$_2$Se$_8^{2+}$(AsF$_6^-$))$_4$(SO$_2$)$_2$ was accomplished by reacting powdered Te and Se with AsF$_5$ or SbF$_5$ in SO$_2$. The novel Te$_2$Se$_6^{2+}$ cation in (Te$_2$Se$_6^{2+}$(SbF$_6^-$)$_2$ is not isostuctural with previously known cations S$_8^{2+}$ and Se$_8^{2+}$. Instead, it has a bicyclo[2.2.2]octane structure with the two Te atoms occupying bridgehead positions (349). The average Te–Se bond is 2.603 Å, significantly longer than the sum of the covalent radii (2.54 Å) and the average Te–Se distance of 2.57 Å in Te$_2$Se$_6^{2+}$(AsF$_6^-$)$_2$. Furthermore, the Se(1)–Se(2) bond is longer than the other Se–Se bonds. Interestingly, the three transannular Se–Se contacts at the cube edges (3.34–3.42 Å) are shorter than the sum of the van der Waals radii, indicating weak cross-ring bonding.

Based on the same principle, adducts Te$_3$S$_3^{2+}$(AsF$_6^-$)$_2$, Te$_2$Se$_4^{2+}$(AsF$_6^-$)$_2$, Te$_2$Se$_4^{2+}$(Sb$_3$F$_{14}^-$)(SbF$_6^-$), Te$_2$Se$_4^{2+}$(AsF$_6^-$)$_2$, Te$_2$Se$_4^{2+}$(AsF$_6^-$)$_2$, Te$_2$Se$_4^{2+}$(SbF$_6^-$)$_2$, and Te$_3$Se$_2^{2+}$(SbF$_6^-$)$_2$ have been prepared. The Te$_3$S$_3^{2+}$ and Te$_2$Se$_4^{2+}$ cations have novel structures that can be described as consisting of a three-membered ring and a five-membered ring fused together or as a boat-shaped six-membered ring with a cross-ring bond corresponding to a bicyclo[3.1.0]hexane-type arrangement.

The trans-Te$_2$Se$_2^{2+}$ dication and the Te$_3$Se$_{1.0}^{2+}$ dication have been also prepared and studied by Raman and IR spectroscopy. The trans-Te$_2$Se$_2^{2+}$ cation in Te$_2$Se$_2^{2+}$(Sb$_3$F$_{14}^-$)(SbF$_6^-$) has Te–Se bond lengths of 2.446 and 2.481 Å and has Se–Te–Se and Te–Se–Te bond angles of 89.1° and 90.9°, respectively. Consequently, it is significantly distorted because of the different sizes of Te and Se. Furthermore, the Te–Se bond lengths are considerably shorter than bond distances in cations Te$_2$Se$_2^{2+}$ (2.525–2.539 Å) and Te$_2$Se$_8^{2+}$ (2.579–2.644 Å). This is consistent with the bonds in trans-Te$_2$Se$_2^{2+}$ having some double bond character. The bonding in the trans-Te$_2$Se$_2^{2+}$ cation is similar to the resonance structures 343 found for the Se$_4^{2+}$ cation. The Te$_3$Se$_{1.0}^{2+}$ dication was found to be a disordered mixture of cations Te$_3$Se$_2^{2+}$, Te$_4^{2+}$, and trans-Te$_2$Se$_2^{2+}$. A disordered mixture of S$_n$Se$_{4-n}^{2+}$
dications was also shown to give a cation with an average composition of $S_{3.0}Se_{1.0}^{2+}$.\textsuperscript{936}

Selenium and tellurium multinuclear NMR studies provided useful structural information for Te–Se polyheteroatom cations.\textsuperscript{937–939}

4.4.4. Mixed Polyheteroatom Cations of Group 15, 16, and 17 Elements

4.4.4.1. Polyheteroatom Cations of Nitrogen and Sulfur. The simplest stable S–N species is the NS$^+$ thiazyl cation.\textsuperscript{940} A convenient synthesis is the reaction of excess AgAsF$_6$ with S$_3$N$_3$Cl$_3$ in SO$_2$.\textsuperscript{941} The bond length of the NS$^+$ cation shows a pronounced temperature dependence (corrected value $= 1.42\, \text{Å}$), and of the two resonance structures N=NS$^+$ is stabilized by ionic interactions.\textsuperscript{942}

Thionitronium ion NS$_2^+$,\textsuperscript{943–945} the sulfur analog of nitronium ion NO$_2^+$ was first obtained by Gillespie and co-workers\textsuperscript{946} [Eq. (4.223)] and an improved synthesis was subsequently reported by Passmore and co-workers\textsuperscript{947} [Eq. (4.224)]. The X-ray crystal structure analysis of the salt NS$_2^+$SbCl$_6^-$ shows a linear centrosymmetric cation with short N=S $\pi$-bondings, nevertheless, the positive charge is delocalized to the S atoms.\textsuperscript{946,948} The experimental bond length of 1.49 Å is well reproduced by calculations.

\[
\begin{align*}
S_7NH & + BCl_3 \xrightarrow{SO_2, -196 \text{ to } -48\, \text{°C}, -HCl} S_7NBCl_2 \xrightarrow{\text{SO}_2, -48\, \text{°C}, -S_8} S_2N^+\text{SbCl}_6^- \quad (4.223) \\
1/8 S_8 + S_4N_4 + 6 \text{AsF}_5 & \xrightarrow{\text{Br}_2, \text{SO}_2, \text{RT}} 4S_2N^+\text{AsF}_6^- + 2\text{AsF}_3 \quad (4.224)
\end{align*}
\]

Several other cations containing both sulfur and nitrogen have cyclic structure. These include the S$_3N_2^+$ cation,\textsuperscript{949–951} S$_3N_2^{2+}$ dication,\textsuperscript{951,952} S$_6N_4^{2+}$ dication,\textsuperscript{944,950} S$_4N_3^+$ cation,\textsuperscript{953} S$_4N_4^{2+}$ dication,\textsuperscript{954} and S$_5N_5^+$ cation.\textsuperscript{955,956}

The S$_3N_2^{2+}$ radical cation has a planar ring and exists only in the S$_3N_2^{2+}$AsF$_6^-$ salt,\textsuperscript{950} whereas in all other salts it is dimeric. The S$_6N_4^{2+}$ dication (350a) consists of two centrosymmetric units with delocalized $6\pi$ electrons held together through strong S=S interactions (2.971 Å).\textsuperscript{944,950} The mixed Se$_4S_2N_4^{2+}$ dication (350b) analogous to S$_6N_4^{2+}$ has also been obtained and characterized.\textsuperscript{957} The length of the diselenide bonds in the AsF$_6^-$ and SbF$_6^-$ salts (2.345–2.369 Å) are close to the single-bond length (2.335 Å), whereas the Se–Se contacts between the two rings are much longer (3.111–3.171 Å).

\[
\begin{align*}
\text{S}_7N\text{H} & + B\text{Cl}_3 \xrightarrow{SO_2, -196 \text{ to } -48\, \text{°C}, -HCl} S_7N\text{BCl}_2 \xrightarrow{\text{SO}_2, -48\, \text{°C}, -S_8} S_2N^+\text{SbCl}_6^- \quad (4.223) \\
1/8 S_8 + S_4N_4 + 6 \text{AsF}_5 & \xrightarrow{\text{Br}_2, \text{SO}_2, \text{RT}} 4S_2N^+\text{AsF}_6^- + 2\text{AsF}_3 \quad (4.224)
\end{align*}
\]
Passmore and co-workers\textsuperscript{952} have prepared the $\text{S}_3\text{N}_2^{2+}$ dication by the cycloaddition of $\text{SN}^+$ to $\text{SNS}^+$. The ion, predicted to be a stable 6\(\pi\)-electron-rich aromatic, dissociates reversibly in $\text{SO}_2$ solution, but it is stable in the solid state. The $\text{S}--\text{N}$ and $\text{S}--\text{S}$ bond distances (1.525–1.584 Å and 2.093 Å, respectively) are close to those found in other $\text{S}_3\text{N}_2$ ring systems. The analogous $\text{SeS}_2\text{N}_2^{2+}$, $\text{SeSN}_2^{2+}$, and $\text{Se}_3\text{N}_2^{2+}$ dications have also been prepared and characterized.\textsuperscript{958–960}

In the planar ring of the $\text{S}_4\text{N}_3^+$ cation, the $\text{S}--\text{S}$ bond distance is 2.066 Å and the $\text{S}--\text{N}$ bond lengths show small variations (1.542–1.569 Å).\textsuperscript{953} The eight-membered ring of the $\text{S}_4\text{N}_4^{2+}$ dication in the $\text{S}_4\text{N}_4^{2+}(\text{AlCl}_4^-)_2$ and $\text{S}_4\text{N}_4^{2+}(\text{FSO}_3^-)_2$ salts has been shown to be planar with $D_{4h}$ symmetry and equal bond lengths, whereas a nonplanar boat-shaped structure has been found for the dication in the $\text{S}_4\text{N}_4^{2+}(\text{SbCl}_6^-)$ salt.\textsuperscript{954} For the $\text{S}_5\text{N}_5^+$ cation, which is a 14\(\pi\)-electron system, heart-shaped\textsuperscript{955} and azulene-like\textsuperscript{956} structures were found and the latter was predicted by calculations.\textsuperscript{961} According to Gillespie et al.\textsuperscript{962} the cation in the $\text{S}_5\text{N}_5^+(\text{SbCl}_6^-)$ salt is planar and its geometry is intermediate between the structures suggested earlier (\textsuperscript{351}).

The ($\text{S}_3\text{N}_2$)$_2\text{N}^+\text{AsF}_6^−$ salt with two identical ($\text{S}_3\text{N}_2$)$_2\text{N}^+$ cations and $\text{AsF}_6^−$ units in the crystal has been prepared by Passmore and co-workers.\textsuperscript{963} In the unique cation 352 the $\text{S}_3\text{N}_2$ rings are connected by a bridging nitrogen attached to a sulfur atom of each ring (S–N–S bond angle = 111.6°). The average bridging S–N bond length is 1.624 Å corresponding to a bond order of 1.47. The two rings are eclipsed with an average S–N bond length of 1.586 Å.

\subsection{Polyheteroatom Cations of Halogens with Oxygen or Nitrogen.}

Lewis acid adducts of chlorine trifluoride oxide ($\text{ClF}_2\text{O}$),\textsuperscript{964,965} chlorine trifluoride dioxide ($\text{ClF}_3\text{O}_2$),\textsuperscript{845,966} and nitrogen trifluoride oxide ($\text{NF}_3\text{O}$)\textsuperscript{967} are all known. They are best described as ClF$^+\text{O}^−$, ClF$^+_2\text{O}^+$, and NF$^+\text{O}^−$, respectively. The spectroscopic properties of these cations have been investigated extensively.\textsuperscript{448,818,845,964–966,968,969}
A new stable nitrogen fluoride oxide, \( \text{N}_3\text{NFO}^+ \) has recently been reported by Christe and co-workers\(^9\)\(^7\)\(^0\) [Eq. (4.225)]. Spectroscopic investigation of the fluoroantimonate salt \((^{14/15}\text{N} \text{ and } ^{19}\text{F} \text{ NMR, Raman})\) showed the presence of two stereo-isomers in agreement with theoretical studies \([\text{B3LYP/G}(2\text{df}), \text{MP2, CCSD(T)} \text{ levels}]\) giving two structures of minimum energy \((\Delta \text{E} \leq 0.6 \text{ kcal mol}^{-1})\). Both structures are planar \((C_s \text{ symmetry})\) and differ in the relative position of the azido moiety and fluorine. The nitrogen chemical shifts indicate a covalent azido group attached to a highly electronegative ligand and a nitrogen bonded to a F and an O. The calculated bond distances and bond angles are given for the \(E-\left[\text{N}_3\text{NFO}^+\right] \) isomer.\(^3\)\(^5\)\(^3\)\(^3\) T h e \(^{19}\text{F} \text{ NMR chemical shifts and the N-O bond lengths of the isomers (1.377 Å for the Z-isomer) differ significantly.}

\[
\begin{align*}
\text{NF}_2\text{O}^+ \text{SbF}_6^- + \text{HN}_3 & \xrightarrow{\text{HF}} -45 \text{ to } 25^\circ \text{C} \xrightarrow{-\text{HF}} \text{N}_3\text{NFO}^+ \text{SbF}_6^- \\
\end{align*}
\]

\[(4.225)\]

Strähle and co-workers\(^9\)\(^7\)\(^1\) were the first to report the synthesis of the dichloronitrioniun ion [Eq. (4.226)]. According to X-ray crystal structure analysis of the hexachloroantimonate salt, which shows a remarkable stability up to 145°C, the cation is almost planar (maximum deviation from the plane is 0.038 Å) and has \(C_s\) symmetry. The N–O bond distance is 1.31 Å, that is, lies between the length of a NO single bond (1.151 Å) and a NO double bond (1.47 Å). This is indicative of a decreased \(\pi\)-bond contribution, which is also reflected in the IR spectrum (stretching vibration at 1650 cm\(^{-1}\) as compared to 1827 cm\(^{-1}\) of phosgene).

\[
\begin{align*}
\text{NCl}_3 + \text{SbCl}_5 + \text{SOCl}_2 & \xrightarrow{\text{CCl}_4} \text{Cl}_2\text{NO}^+ \text{SbCl}_5^- + \text{SCl}_2 \\
\end{align*}
\]

\[(4.226)\]

An improved method developed by Minkwitz et al.\(^9\)\(^7\)\(^2\) allowed to obtain other salts [Eq. (4.227)]. The structure of the cation was characterized by vibrational spectroscopy, \(^{14}\text{N} \text{ NMR} \) (a single peak at \(6^{14}\text{N} \ -282 \) from \(\text{CH}_3\text{NO}_2\)), and by \textit{ab initio} theory.

\[
\begin{align*}
2\text{ONCl} + \text{Cl}_2 + 3\text{MF}_5 & \xrightarrow{\text{SO}_2} -70^\circ \text{C} \xrightarrow{-70^\circ \text{C}} 2\text{Cl}_2\text{NO}^- \text{MF}_6^- + \text{MF}_3 \\
\end{align*}
\]

\[(4.227)\]

An ionic structure for the complex between \(\text{NF}_3\text{O} \) and \(\text{AsF}_5\) was suggested by Bartlett et al.,\(^9\)\(^7\)\(^3\) which was subsequently proved by Christe and Maya\(^9\)\(^6\)\(^7\) by preparing and characterizing (IR, X-ray) stable salts [Eq. (4.228)]. The \(^{19}\text{F} \text{ NMR spectrum of} \)
ion F$_2$NO$^+$ shows a triplet with equal intensity and line width ($\delta^{19}$F -331, $J_{\text{N}-F} = 250$ Hz), and the $^{14}$N NMR shows a singlet ($\delta^{14}$N 281). Ion F$_2$NO$^+$ has also been prepared by fluorination with XeF$^+$ [Eq. (4.229)].

$$\text{NF}_3\text{O} + \text{HF} + \text{SbF}_5 \rightarrow_{-78^\circ C} \text{F}_2\text{NO}^+\text{M}^- \leftarrow \text{NF}_3\text{O} + \text{MF}_n$$

$$M = \text{BF}_4, \text{B}_2\text{F}_7, \text{AsF}_6, \text{SbF}_6 \quad \text{MF}_n = \text{BF}_3, \text{AsF}_5$$

(4.228)

$$\text{ONF} + \text{XeF}^+\text{MF}_6^- \rightarrow_{-50^\circ C} \text{F}_2\text{NO}^+\text{MF}_6^- + \text{Xe}$$

(4.229)

The calculated geometric parameters [B3LYP/6-311 + G(2d,p) level of theory] of the ion F$_2$NO$^+$ ($\text{N}-\text{F} = 131.2$ Å, $\text{N}-\text{O} = 112.9$ Å, $\text{F}-\text{N}--\text{F}$ angle = 108.4°, $\text{F}-\text{N}--\text{O}$ angle = 125.8°) deviate considerably from those determined by Christe and co-workers for the F$_2$NO$^+$AsF$_6^-$ salt ($\text{N}-\text{F} = 124.5$ Å, $\text{N}-\text{O} = 119.0$ Å, $\text{F}-\text{N}--\text{F}$ angle = 115.9°, $\text{F}-\text{N}--\text{O}$ angle = 122.1°). This suggests O/F disorder and refinement of the structure with variable occupancy factors resulted in values with good agreement with those predicted by theory ($\text{N}-\text{F} = 128.4$ Å, $\text{N}-\text{O} = 111.4$ Å, $\text{F}-\text{N}--\text{F}$ angle = 107.9°, $\text{F}-\text{N}--\text{O}$ angle = 126.0°).

The mixed halonitronium ion ClFNO$^+$ has been obtained by Minkwitz et al. by oxidative fluorination of ONCl [Eq. (4.230)]. The ion has much lower stability than the difluoro analog. Subsequently, however, the validity of the structure determination of both Cl$_2$NO$^+$ and ClFNO$^+$ was questioned on the basis of large discrepancies between experimental and theoretical vibrational spectra.

$$\text{ONCl} + \text{N}_2\text{F}^+\text{AsF}_6^- \rightarrow_{-78^\circ C} \text{ClFNO}^+\text{AsF}_6^- + \text{N}_2$$

(4.230)

Fluorination and methylation have been used to synthesize related fluorinated nitronium ions [Eq. (4.231)]. The trifluoromethyl(methyl)nitronium ion ON(Me)CF$_3^+$ exits in the keto form in solution, but X-ray crystal structure data indicate that the enol form HON(CH$_2$)CF$_3^+$ exists in the solid state stabilized by a hydrogen bond between the enolic OH group and one of the fluorines of the counterion.

$$\text{CF}_3\text{NO} \rightarrow_{\text{CCl}_3\text{F}, -35^\circ C} \text{N}_2\text{F}^+\text{AsF}_6^- \rightarrow \text{ON(}\text{CF}_3\text{)}^+\text{F}^+\text{AsF}_6^- + \text{N}_2$$

(4.231)

### 4.4.4.3. Polyheteroatom Cations of Chalcogens with Halogens.

A number of binary polyheteroatom cations of Group 6 and 7 elements have been prepared and characterized.
The $S_2I_4^{2+}$ and $Se_2I_4^{2+}$ dications have been studied extensively. The $S_2I_4^{2+}$ dication has been prepared by Passmore and co-workers [Eq. (4.232)]. The dication in $S_2I_4^{2+}(SbF_6)^-$ consists of two planar quadrilateral $S_2I_2$ units joined at the common $S\cdots S$ bond ($I\cdots I$ bond angle $= 90.38\,^\circ$) (354). It has $C_2v$ symmetry and a distorted trigonal-prism-like shape. The dication in $S_2I_4^{2+}(AsF_6)^-$ shows a significant difference: The $S\cdots S$ bond is not parallel with the $I\cdots I$ bonds and, consequently, has $C_2$ symmetry. The $S\cdots S$, $I\cdots I$, and $S\cdots I$ bond distances in $S_2I_4^{2+}(SbF_6)^-$ (1.818, 2.571, and 2.993 Å, respectively) correspond to bond orders of 2.7, 1.4, and 0.1, respectively. The $S_2I_4^{2+}$ cation, therefore, can be considered to contain an $S_2$ unit of bond order 2.33 and two $I_2^{2+}$ units of bond order 1.33 with a total $\pi$-bond order of 2, held together by a weak interaction. The positive charge is delocalized evenly over all atoms.

![Diagram](image-url)

The $S_2I_4^{2+}$ dication, synthesized in a similar way, has a shape similar to that of the $S_2I_4^{2+}$ dication and a long Se–Se bond (2.841 Å). In sharp contrast, however, the bonding of $Se_2I_4^{2+}$ can be described as a weak dimer of two $SeI_2^{2+}$ units (355) with evenly delocalized positive charge. According to recent quantum chemical calculations (MPW1PW91 method), the $Se_2I_4^{2+}$ dication has aromaticity resulting from through-space conjugation, analogous to transition states of some pericyclic reactions.

$Y_3X_3^{3+}MF_6^{-}$ salts ($Y = S$, $Se$, $X = Cl$, $Br$, $M = As$, $Sb$) have been synthesized and characterized by Raman and $^{77}Se$ NMR spectroscopy, and X-ray crystallography [Eq. (4.233)]. The $Se_3Cl_3^{3+}$ cation adopts a structure with an intracationic $Se\cdots Cl$ contact (3.289 Å) and substantial $Se\cdots Se$ bond alternation (2.191 and 2.551 Å) resulting from the delocalization of the positive charge with resonance structure 356b. The crystal structure of $S_3Cl_3^{3+}AsF_6^{-}$ contains two crystallographically different disordered cations. The disorder arises from the superimposition of the two ordered cations 357a and 357b.
The Se$_3$Br$_3^+$ cation gives three resonances of equal intensity in the $^{77}$Se NMR spectra at $-70^\circ$C ($\delta^{77}$Se 1065, 1263, 1735). At $-40^\circ$C the two peaks at $\delta^{77}$Se 1065 and 1263 coalesce into a broad peak ($\delta^{77}$Se 1184) consistent with an intercationic exchange process rendering Se(1) and Se(3) equivalent ($358a$ and $358b$). The short S–S and Se–Se bond distances of these cations are indicative of $3p_\pi$–$3p_\pi$ and $4p_\pi$–$4p_\pi$ bonds, respectively.

Passmore and co-workers have prepared the Se$_6$I$_2^{2+}$ dication $359$ [Eq. (4.234)]. X-ray crystal structure analysis showed that the dication has $C_i$ symmetry and contains a hexaselenium ring in the chair conformation with iodine atoms in endo position ($359$). The Se–Se bonds of di- and tricoordinate selenium atoms alternate significantly [average Se(1)–Se(2) and Se(2)–Se(3) bond lengths are 2.475 and 2.227\,\text{Å}, respectively]. The reaction of Se, I$_2$, and AsF$_5$ in a molar ratio of 12:1:3 results in the formation of the polymeric (Se$_6$I))$_n^+$,n(AsF$_6^-$) salt, and the reaction of Se with I$_2$Sb$_2$F$_{11}$ yields (Se$_6$I))$_n$·n(SbF$_6^-$). Both salts contain polymeric strands of (Se$_6$I))$_n$ species. The geometry of the cationic unit is similar to that of the Se$_6$I$_2^{2+}$ dication with iodine atoms connecting the Se$_6$ rings ($360$). The Se–I–Se bond is almost linear (bond angles are 173.7$^\circ$ and 174.2$^\circ$ for the AsF$_6^-$ and SbF$_6^-$ salts, respectively) and can be considered a three-center four-electron bond. The (Se$_6$I$^+$)$_n$ strands are joined together by weak intercationic interactions.

\begin{equation}
6\text{Se} + \text{I}_2 + 3\text{AsF}_5 \overset{\text{SO}_2}{\longrightarrow} \text{Se}_6\text{I}_2^{2+}(\text{AsF}_6^-)_2 \quad \text{Se}_6(\text{AsF}_6)_2 + \text{Se}_3\text{AsF}_6
\end{equation}

(4.234)
The general synthetic route shown in Eq. (4.235) has been used to prepare $S_7X^+MF_6^-\ (M = As, Sb)$ salts. The stability of the cations decreases in the order $I > Br > Cl > F$. The X-ray structure of the $S_7I^+$ and $S_7Br^+$ cations was obtained. Both cations were shown to have a seven-membered sulfur ring in a slightly distorted chair conformation with markedly varying $S-C$ bond distances ($1.900–2.389 \text{ Å}$ for $S_7I^+\text{SbF}_6^-$). The $S-I (2.30–2.37 \text{ Å})$ and $S-Br (2.11 \text{ Å})$ bond lengths are slightly shorter than the sum of the van der Waals radii (2.37 and 2.18 Å, respectively). All $S_7I^+$ cations have I$^rF$ contacts with the SbF$_6^-$ anions in the solid state.

$$S_8^{2+}(\text{MF}_6^-)_2 + \text{EX} \xrightleftharpoons[SO_2]{} S_7X^+\text{MF}_6^- + \text{EMF}_6^- + 1/8S_8$$  (4.235)

$M = \text{As, Sb}$
$E = \text{Na, K}$
$X = \text{F, Cl, Br, I}$

4.5. CATIONS OF GROUP 6–12 ELEMENTS

4.5.1. Homoleptic Metal Carbonyl Cations

The first homoleptic carbonyl cations of Group 7 metals with the general formula $[\text{M(CO)}_6]^+$ ($\text{M} = \text{Mn, Tc, Re}$) were generated by Fischer and co-workers and Hieber and co-workers in the 1960s applying halide abstraction by Lewis acids [Eq. (4.236)].

$$\text{M(CO)}_5X + \text{AlX}_3 + \text{CO} \xrightarrow[85–100^\circ\text{C}, 300 \text{ atm CO}]{\text{H}_2\text{SO}_4\text{F}} [\text{M(CO)}_6]^+\text{AlX}_4^-$$  (4.236)

$M = \text{Mn, Tc, Re}$
$X = \text{Cl, Br}$

The method, however, could not be extended to the synthesis of other metal carbonyl cations. Thus, Group 7 metal carbonyl cations remained isolated examples until 1990, when Aubke and co-workers generated $[\text{Au(CO)}_2]^+$ in HSO$_4$F. This was followed by the isolation and characterization of the salts $[\text{Au(CO)}_2]^+\text{Sb}_2\text{F}_{11}^-$ and $[\text{Hg(CO)}_2]^2+\text{(Sb}_2\text{F}_{11})^-$. Since then, stable salts of Group 6–12 metal carbonyl cations with the SbF$_6^-$ or Sb$_2$F$_{11}^-$ anion have been isolated and characterized mainly by Aubke’s group (Figure 4.4). These cations with the general formula $[\text{M(CO)}_n]^m^+\ (n = 2, 4, 6; \text{m} = 1–3)$ have mainly $\sigma$-bonded CO ligands. In addition, thermally unstable polycarbonyl complexes $[\text{M(CO)}_n]Y$ of Cu and Ag are also known ($n = 1–4$); however, the nature of the $M-Y$ bond, in most cases, is covalent.

Versatile synthetic routes are available to prepare metal carbonyl cations in superacidic media. The most successful methods include reductive carbonylation of metal fluorosulfates or fluorides [Eqs. (4.237) and (4.238)].
method was also applied in the synthesis of \([\text{Au(CO)}_2]^+\text{Sb}_2\text{F}_{11}^-\) from \(\text{Au(SO}_3\text{F)}_3\) and \(\text{AuF}_3\), and the corresponding metal chlorides could also be used as starting materials to prepare Au, Pd, and Pt fluoroantimonates. In contrast to reductive carbonylation, the oxidation state of the metal remains unchanged in solvolytic carbonylation [Eqs. (4.239) and (4.240)].

\[
\begin{align*}
\text{Pt(SO}_3\text{F)}_4 + 5\text{CO} + 8\text{SbF}_5 & \quad \overset{\text{HF-SbF}_5}{\text{25°C, 1 day}} \quad [\text{Pt(CO)}_4]^2+ (\text{Sb}_2\text{F}_{11}^-)_2 + 2\text{Sb}_2\text{F}_9(\text{SO}_3\text{F}) + \text{S}_2\text{O}_5\text{F}_2 \quad (4.237) \\
2\text{IrF}_6 + 15\text{CO} + 6\text{SbF}_5 + 8\text{HF} & \quad \overset{\text{HF-SbF}_5}{\text{25°C, 28 h}} \quad [\text{Ir(CO)}_6]^3+ (\text{SbF}_6^-)_3 \cdot 4\text{HF} + 3\text{COF}_2 \quad (4.238) \\
\text{Hg(SO}_3\text{F)}_2 + 2\text{CO} + 8\text{SbF}_5 & \quad \overset{\text{SbF}_5}{\text{100°C, 1 h}} \quad [\text{Hg(CO)}_2]^2+ (\text{Sb}_2\text{F}_{11}^-)_2 + 2\text{Sb}_2\text{F}_9(\text{SO}_3\text{F}) \quad (4.239) \\
\text{cis-M(CO)}_2(\text{SO}_3\text{F})_2 + 2\text{CO} + 8\text{SbF}_5 & \quad \overset{\text{HF-SbF}_5}{\text{25°C, 1 day}} \quad [\text{M(CO)}_4]^2+ (\text{Sb}_2\text{F}_{11}^-)_2 + 2\text{Sb}_2\text{F}_9(\text{SO}_3\text{F}) \quad \text{M = Pt, Pd} \quad (4.240)
\end{align*}
\]

Oxidative reactions are the method of choice in the generation of cations of Group 6, 8, and 9 metals [Eq. (4.241)]. The \(\text{fac-Rh(CO)}_3(\text{FSO}_3\text{)}_3\) complex used in the synthesis of the Rh(I) salt \(361\) [Eq. (4.242)] was prepared from the solvated \([\text{Rh(CO)}_4]^+\) cation generated from \([\text{Rh(CO)}_2\text{Cl}]_2\). All procedures are performed under a CO atmosphere (1–2 atm).

\[
\begin{align*}
2\text{Fe(CO)}_5 + 2\text{CO} + \text{XeF}_2 + 4\text{SbF}_5 & \quad \overset{\text{SbF}_5}{\text{50°C, 2 days}} \quad 2[\text{Fe(CO)}_6]^2+ (\text{Sb}_2\text{F}_{11}^-)_2 + \text{Xe} \quad (4.241) \\
\text{fac-Rh(CO)}_4(\text{FSO}_3\text{)}_3 & \quad \overset{1. \text{CO, HSO}_3\text{F}, \text{25°C}, 2. \text{CO, HF-HSO}_3\text{F}, -196°C \text{to} -40°C}{\text{25°C, 1 day}} \quad [\text{Rh(CO)}_4]^+ \text{Sb}_2\text{F}_{11}^- \quad (4.242)
\end{align*}
\]
The stable, isolable salts have been thoroughly characterized by vibrational and $^{13}$C NMR spectroscopy, and molecular structures have also been elucidated.\textsuperscript{1001,1002} The geometry of the cationic complexes depends on the coordination number and electron configuration of the metal ion: Metal ions with coordination number 2 ($d_{10}$ electron configuration) and 4 ($d_{8}$ electron configuration), respectively, form linear ($D_{\infty h}$ symmetry) and square-planar ($D_{4h}$ symmetry) cationic complexes, whereas complexes of metals with $d_{6}$ electron configuration (coordination number 6) are octahedral ($O_h$ symmetry). Illustrative of each class is the XRD structure of linear $[\text{Au(CO)}_2]^+\text{Sb}_2\text{F}_{11}^-/\text{C}_{0}$\textsuperscript{999} and $[\text{Hg(CO)}_2]^2+\text{Sb}_2\text{F}_{11}^-/\text{C}_{0}$\textsuperscript{1000}, square-planar $[\text{M(CO)}_4]^2+\text{Sb}_2\text{F}_{11}^-/\text{C}_{0}$ (M = Pd, Pt),\textsuperscript{1003} and octahedral $[\text{M(CO)}_6]^{2+}(\text{Sb}_2\text{F}_{11}^-)_2$ (M = Fe, Ru, Os)\textsuperscript{1007,1009} and $[\text{Ir(CO)}_6]^3+\text{Sb}_2\text{F}_{11}^-/\text{C}_{0}$\textsuperscript{1004} metal carbonyl cations. The molecular geometries are very regular and only slight angular distortions are detected. In the $[\text{Fe(CO)}_6]^+$ cation, for example, the C–Fe–C angles deviate from 90° by 0.2–1.1° and the Fe–C–O angles are between 177.5° and 179.4°.

The C–O bond lengths (about 1.1 Å) are unusually short, which is a common feature of all σ-bonded metal carbonyl cations. This is related to the fact that M–CO π backbonding is almost absent, resulting also in increased M–C bond lengths. For so-called superelectrophilic cations (metals with oxidation states +2 and +3) the M–C bond distances are about 2.0 Å. As a result, very high $\nu$(CO)\textsubscript{av} values are detected (up to about 2280 cm\textsuperscript{-1}), indicating high polarization of the C–O bond and electrophilic nature of carbon. The strength of the C–O bond in $[\text{M(CO)}_n]^{m+}$ homoleptic carbonyl cations is found to be proportional to the charge $m$ and inversely proportional to the coordination number $n$.\textsuperscript{1002} In many salts, significant intercationic contacts are observed between the electrophilic carbon and fluorine, whereas M–F interactions are negligible. These observations are supported by DFT calculations.

In addition to the varied homoleptic carbonyl cations isolated as undecafluorodianantiumates (V), salts with other counteranions are also known. Two examples are $[\text{Co(CO)}_5]^+\text{[(CF}_3)_3\text{BF}]^-$ and $[\text{Rh(CO)}_4]^+\text{1-Et-CB}_{11}\text{F}_{11}^-$. The Co salt contains the univalent metal carbonyl cation, which is the first example of a trigonal-bipyramidal structure ($D_{3h}$ symmetry).\textsuperscript{1010} It is synthesized by oxidation of the Co$_2$(CO)$_8$ cluster with H$_2$F$^+$ [Eq. (4.243)]. There are no significant interactions between cations and anions, and the Co–C$_{eq}$ bond is somewhat shorter than the Co–C$_{ax}$ bond (1.826 Å versus 1.853 Å). The formation of the Rh salt was first observed by differential total reflectance FT–IR in a rather unexpected reaction between the solid complex 362 and CO [Eq. (4.244)], and then it was independently prepared according to Eq. (4.245).\textsuperscript{1011} The cation has $D_{4h}$ symmetry and, interestingly, there is a contact between Rh and one of the hydrogens of the methyl group of the carborane anion.

\[
[\text{Co}_2\text{(CO)}_6] + 2(\text{CF}_3)_3\text{BCO} + 2\text{HF} \xrightarrow{\text{HF, CO (2 bar)}} 2[\text{Co(CO)}_5]^+\text{[(CF}_3)_3\text{BF}]^+ + \text{H}_2
\]

(4.243)
Despite the fact that CO is reversibly bound to Ag(I), Strauss and co-workers\textsuperscript{1012} succeeded in isolating crystalline silver carbonyl complexes at low temperature under a CO atmosphere and studying the crystal structure of [Ag(CO)]\textsuperscript{+}[B(OTeF\textsubscript{5})\textsubscript{4}]\textsuperscript{−} and [Ag(CO)\textsubscript{2}]\textsuperscript{+}[B(OTeF\textsubscript{5})\textsubscript{4}]\textsuperscript{−}.

The synthesis and characterization of heptachloroaluminate and -gallate complexes of Rh(I) [Eq. (4.246)]\textsuperscript{1008} and the first tetrafluoroborate salts have recently been reported. Oxidative decarbonylation with XeF\textsubscript{2} was used for the synthesis of the Fe salt as shown in Equation (4.241), whereas the [M(CO)\textsubscript{6}]\textsuperscript{+}BF\textsubscript{4}\textsuperscript{−} (M = Ru, Os) derivatives were obtained by oxidative decarbonylation with F\textsubscript{2} followed by solvolytic carbonylation [Eq. (4.247)].\textsuperscript{1013} Experimental studies (XRD, FT–IR) show that structural and spectroscopic properties of the cations [M(CO)\textsubscript{6}]\textsuperscript{+} (M = Fe, Ru, Os) are independent of the anion.

4.5.2. Other Cations of Group 6–12 Elements

A group of metal carbonyl cations with Sb\textsubscript{2}F\textsubscript{11}\textsuperscript{−} as counteranion generated in superacids include [η\textsuperscript{6}-(C\textsubscript{6}H\textsubscript{6})Rh(CO)\textsubscript{2}]\textsuperscript{+}, [M(CO)\textsubscript{5}Cl]\textsuperscript{+} (M = Rh, Ir), [W(CO)\textsubscript{6}(FSbF\textsubscript{5})]\textsuperscript{+}, and the polymeric {[}[Mo(CO)\textsubscript{4}]\textsubscript{2}(cis-\mu-F\textsubscript{2}SbF\textsubscript{4})\textsubscript{6}].\textsuperscript{1014} The PF\textsubscript{6}\textsuperscript{−} salt of the hexamethylbenzene analog of cation 362 was first reported in 1982 without structural characterization.\textsuperscript{1015} Strauss and co-workers\textsuperscript{1011} have isolated the carborane anion salt [Eq. (4.248)] and found that it has two nearly identical cations of C\textsubscript{2}v symmetry in the crystal state. The C–Rh–C angle in the Rh(CO)\textsubscript{2} moiety is \(\sim\)90° deduced from the equal intensities of the two ν(CO) bands. The molecular structure of the isostructural Rh and Ir cations show C\textsubscript{4v} symmetry and nearly identical bond angles and bond lengths.\textsuperscript{1008,1016} The unusually long M–C and short C–O bonds and high CO stretching frequencies are characteristic features observed for the corresponding homoleptic metal carbonyl cations as well.
Two-electron oxidation of W(CO)\textsubscript{6} with Sb\textsubscript{2}F\textsubscript{5} in HF–SbF\textsubscript{5} to give [W(CO)\textsubscript{6}(FSbF\textsubscript{5})\textsuperscript{2\textsuperscript{+}}]\textsuperscript{+} Sb\textsubscript{2}F\textsubscript{11\textsuperscript{−}} in quantitative yield without loss of CO is unprecedented.\textsuperscript{1017} The cation is seven-coordinated with a distorted C\textsubscript{2v} capped trigonal prismatic structure. FSbF\textsubscript{5} is tightly coordinated to W with nearly equal W–F and Sb–F bond lengths. Mo(CO)\textsubscript{6} reacts with SbF\textsubscript{5} in a very similar manner to form the fluoro-bridged product [Mo(CO)\textsubscript{6}(FSbF\textsubscript{5})]\textsuperscript{2\textsuperscript{+}}Sb\textsubscript{2}F\textsubscript{11\textsuperscript{−}}.\textsuperscript{1014} This, however, undergoes condensation with partial elimination of CO and SbF\textsubscript{5}, and cis-μ-F\textsubscript{2}SbF\textsubscript{4} bridges are formed to yield polymeric \{[Mo(CO)\textsubscript{4}](cis-μ-F\textsubscript{2}SbF\textsubscript{4})\textsuperscript{3\textsuperscript{+}}\}\textsubscript{m}(Sb\textsubscript{2}F\textsubscript{11\textsuperscript{−}})\textsubscript{x}. The polymerization of the tungsten analog, in turn, requires elevated temperature (>100°C). A comparison of XRD data shows a rather wide range of bond parameters for the cations, but the differences are less pronounced for the Mo(CO)\textsubscript{4} moiety.

During the synthesis of the [Os(CO)\textsubscript{6}]\textsuperscript{2\textsuperscript{+}}(Sb\textsubscript{2}F\textsubscript{11\textsuperscript{−}})\textsubscript{2} salt by the reductive carboxylation of Os(SO\textsubscript{3}F), OsF\textsubscript{6}, or OsO\textsubscript{4}, Aubke and co-workers\textsuperscript{1018} observed a band at 2253 cm\textsuperscript{−1} in the IR spectra of the products. They used a modified synthesis [Eq. (4.249)] to isolate the extremely moisture-sensitive compound 363. The cation identified by vibrational spectroscopy has octahedral geometry with trans oxygen atoms. Experimental frequencies agree well with calculated data (gradient-corrected DFT calculations at the BP86/ECP2 level).

\[
\text{OsO}_4 + 5 \text{CO} \xrightarrow{\text{SbF}_5, 1.5 \text{ atm CO}} \text{25°C} [\text{OsO}_2(\text{CO})_4]^+ \text{Sb}_2\text{F}_{11^-} + \text{SbOF}_3 + \text{CO}_2 \quad (4.249)
\]

Schrobilgen and co-workers\textsuperscript{1019} have prepared oxafluoro cations of Tc, Re, and Os as Sb\textsubscript{2}F\textsubscript{11\textsuperscript{−}} and AsF\textsubscript{6\textsuperscript{−}} salts and characterized them by X-ray diffraction and Raman and NMR spectroscopy. The Tc\textsubscript{2}O\textsubscript{2}F\textsubscript{9\textsuperscript{+}} cation contains two fluorine-bridged square pyramidal TeOF\textsubscript{4} groups with the F bridge trans to the oxygen atoms (Tc–F–Tc angle = 158.2°, bridging Tc–F bond distances = 2.061 Å and 2.075 Å).\textsuperscript{1019} Geometric and spectral characteristics (vibrational frequencies, \textsuperscript{19}F and \textsuperscript{99}Tc NMR data) calculated by local DFT are in good agreement with experimental values. According to the \textsuperscript{19}F NMR spectrum, the Re\textsubscript{2}O\textsubscript{4}F\textsubscript{5\textsuperscript{+}} cation consists of two ReO\textsubscript{2}F\textsubscript{3} moiety with a bridging fluorine.\textsuperscript{1020} In the crystal structure of [μ-F(OsO\textsubscript{2}F\textsubscript{3})\textsubscript{2}]\textsuperscript{+}Sb\textsubscript{2}F\textsubscript{11\textsuperscript{−}} the di-nuclear fluorine-bridged (F\textsubscript{3}O\textsubscript{2}Os–F–OsO\textsubscript{2}F\textsubscript{3}) cation has a distorted octahedral cis-dixo arrangement and the fluorine bridge is trans to one of the oxygen atoms of each OsO\textsubscript{2}F\textsubscript{3} unit (Os–F–Os angle = 155.2°, Os–F bond distance = 2.086 Å).\textsuperscript{1021}

Varied salts of the OsO\textsubscript{3}F\textsuperscript{+} cation were generated by reacting osmium trioxide difluoride with AsF\textsubscript{5} and SbF\textsubscript{5} in HF solvent.\textsuperscript{1022} The OsO\textsubscript{3}F\textsuperscript{+}Y\textsuperscript{−} (Y = AsF\textsubscript{6}, SbF\textsubscript{6}) have distorted C\textsubscript{3v} symmetry with one Os–O bond significantly

\[
[Rh(CO)_2Cl]_2 + [Ag(C_6H_5)]^+ 1-Et-CB_{11}F_{11^-} \xrightarrow{\text{CH}_2\text{Cl}_2} [\eta^6-C_6H_6]Rh(CO)_2]^+ 1-Et-CB_{11}F_{11^-}
\]

(4.248)
longer (1.711 Å and 1.708 Å for the AsF$_6^-$ and SbF$_6^-$ salts, respectively). The cations are bridged through a fluorine of the anion and two such cation–anion pairs form a cyclic dimer by additional fluorine bridges. The cation–anion pairs in the cyclic dimer of the solvated salt OsO$_3$F$^+$(HF)$_2$AsF$_6$– are linked together by two hydrogen-bonded (HF)$_2$ moieties. One Os–O bond of the cation is much shorter (1.666 Å). The X-ray structure of the OsO$_3$F$^+$(HF)SbF$_6$– salt contains helical (FO$_3$O–FH–FSbF$_5$)$_n$ chains. In sharp contrast, the cations are well-separated from the cis-fluorine-bridged Sb$_3$F$_{16}$– anion in the crystals of the OsO$_3$F$^+$Sb$_3$F$_{16}$– salt.

Acetonitrile complexes of Pd, Pt, and Au were prepared by complete ligand exchange of the corresponding homoleptic metal carbonyl salts under solvolysis conditions with the concomitant conversion of the dioctahedral anion Sb$_2$F$_{11}$– into SbF$_6$–. The [Au(MeCN)$_2$]$^+$SbF$_6$– salt formed is not solvated, in contrast to the resulting Pd and Pt salts [Eq. (4.250)]. The Pd and Pt cations are square planar with a slight deviation of the N–C–C group from linearity (177°), whereas the molecular structure of the [Au(MeCN)$_2$]$^+$ cation is highly regular.

The Re oxafluoro acetonitrile complex prepared by Schrobilgen and co-workers [Eq. (4.251)] and characterized by spectroscopic methods ($^1$H, $^{13}$C, $^{19}$F NMR and Raman) has a pseudooctahedral cis-dioxo arrangement. The acetonitrile ligands are trans to the oxygens and the fluorines are trans to each other.

The homoleptic carbonyl salt [Hg(CO)$_2$]$^+$(Sb$_2$F$_{11}$–)$_2$ reacts with traces of water in the HF–SbF$_5$ superacid to yield the bis-aqua solvate [Hg$_2$(OH)$_2$]$^+$(SbF$_6$–)$_2$. 4 HF. The cation is almost linear with nearly C$_2$v symmetry. The Hg–Hg and Hg–O bond distances are 2.4917 Å and 2.148 Å, respectively, and the O–Hg–Hg bond angle is 177.6°.

The [Au(PF$_3$)$_2$]$^+$Sb$_2$F$_{11}$– salt was synthesized from the corresponding homoleptic dicarbonyl complex by ligand exchange with PF$_3$ and reductive phosphorylation of Au(SO$_3$F)$_3$ with excess PF$_3$ in HSO$_3$F. Spectroscopic data ($^{19}$F and $^{31}$P NMR, FT-IR, Raman) suggest a linear structure, predominantly covalent Au–P bonding, and highly reduced π backdonation. The crystal structure of [(PF$_3$)$_2$Au]$^+$SbF$_6$– supports the above conclusions.

The first metal–xenon compound with direct Au–Xe bonds has been reported by Seidel and Seppelt [Eq. (4.252)]. The salt crystallizes in two crystallographic modifications differing in cation–anion interactions. In each form the cation is a regular square. In the triclinic modification the Au–Xe bond lengths are between 2.7330 Å and 2.7779 Å and there are three weak interionic contacts (Au–F
distances = 2.671 Å, 2.950 Å, 3.153 Å). The interionic contacts in the tetragonal modification are weaker (Au···F distance = 2.928 Å).

\[
\text{AuF}_3 + 6\text{Xe} \xrightarrow{\text{HF–SbF}_5, (2:1)} [\text{AuXe}_4]^+ (\text{Sb}_2\text{F}_{11}^-) + \text{Xe}_2^+ \quad (4.252)
\]

When excess Xe was pumped off from the reaction mixture at −78°C, the \([\text{cis-AuXe}_2]^{2+}(\text{Sb}_2\text{F}_{11}^-)_2\) was isolated in the form of violet-black crystals.\(^{1028}\) The cation has two Xe and two F contacts with slightly shorter Au–Xe bond lengths (2.658 Å and 2.671 Å) and rather short Au···F contacts (2.181 and 2.238 Å). Seppelt and coworkers were also successful in isolating \([\text{trans-AuXe}_2]^{2+}(\text{Sb}_2\text{F}_{11}^-)_2\) and \([\text{Au}_2\text{Xe}_2\text{F}]^{3+}(\text{Sb}_2\text{F}_{11}^-)_3\) with the Au\(^{2+}\) center residing in a square-planar environment. In the latter case, the cation has a Z-shaped \([\text{Xe}–\text{Au}–\text{F}–\text{Au}–\text{Xe}]^3^+\) ion. In addition to these gold salts, Hwang and Seppelt\(^{1030}\) also isolated the unique \([\text{Au(HF)}_2]^{2+}(\text{Sb}_2\text{F}_{11}^-)\cdot 2\text{HF}\) by reducing AuF\(_3\) in HF–SbF\(_5\) upon UV irradiation. It is a rare example of compounds with HF as ligand with square-planar AuF\(_4\) units in the crystal structure.

In all salts discussed above the cation has a gold(II) center. The only example of a cation with a gold(III) center is \([\text{trans-AuXe}_2\text{F}]^{2+}(\text{Sb}_2\text{F}_{11}^-)(\text{SbF}_6^-)\).\(^{1028}\) The Au–Xe distances (2.593 Å and 2.619 Å) are markedly shorter than those in the Au\(^{2+}\) complexes. In further studies Seppelt and co-workers prepared two gold(I) complexes. The very strong cation–anion contacts in \([\text{F}_3\text{As})\text{Au}^{+}\text{SbF}_6^-\) through one fluorine atom allow the possible description as \(\text{F}_3\text{As}–\text{Au}–\text{F}–\text{Au}–\text{Xe} \) \(^{1026}\) This was then transformed to \([\text{F}_3\text{As})\text{AuXe}]^{+}\text{SbF}_2\text{F}_{11}^-\) [Eq. (4.253)], which is stable at room temperature.\(^{1031}\) The As–Au–Xe moiety is almost linear (173.26°), the Au\(^{+}\)–Xe bond is similar to the Au\(^{3+}\)–Xe distance but much shorter than the Au\(^{2+}\)–Xe bonds, and there are only weak interionic interactions (the shortest Au···F separation is 2.848 Å).

\[
([\text{F}_3\text{As})\text{Au}]^{+}\text{SbF}_6^- + \text{Xe} \xrightarrow{\text{HF–SbF}_5} \text{HF–SbF}_5 \xrightarrow{-196°C to RT then to -50°C} ([\text{F}_3\text{As})\text{AuXe}]^{+}\text{Sb}_2\text{F}_{11}^- \quad (4.253)
\]

Additional Au(I) cation complexes with phosphane ligands are the binuclear halogen-bridged complexes \(\{[(\text{R}_3\text{P})\text{Au})_2\text{X}](\text{BF}_4^-)\) \(\text{R} = \text{Et}, \text{Ph}, \text{ortho}-\text{tolyl}, \text{Bn}, \text{mesityl}, \text{X} = \text{Cl}, \text{Br}, \text{I}\).\(^{1032}\) The molecular structure of \(\{[(\text{Ph}_3\text{P})\text{Au})_2\text{Br}](\text{BF}_4^-)\) shows a V-shape structure (Au–Br–Au bond angle = 96.83°) and a quasi-linear coordination of the gold atoms (P–Au–Br = 177.87°). The Au–Au distance (3.6477 Å) indicates negligible interactions between the gold atoms. These data differ considerably from those observed earlier for \(\{[(\text{Ph}_3\text{P})\text{Au})_2\text{Cl}](\text{ClO}_4^-)\).\(^{1033}\) The Au–Br–Au bond angle is much smaller (81.7°) and the Au–Au distance is significantly shorter (3.06 Å), indicating intramolecular bonding interactions.

Hg\(^{2+}\) ions, which are isoelectronic with Au\(^{+}\), reacting with SbF\(_5\) in the presence of xenon above room temperature yield the stable \([\text{HgXe}]^{2+}(\text{Sb}_2\text{F}_{11}^-)(\text{Sb}_2\text{F}_{11}^-)\) salt.\(^{1031}\) The salt has a highly distorted capped structure with Xe in the capping position. The Hg–Xe bond length (2.7693 Å) is similar to that of the Au–Xe bond distance.
in AuXe₄²⁺ and there are six Hg⁻·F contacts with distances between 2.279 Å and 2.594 Å.

4.6. MISCELLANEOUS CATIONS

4.6.1. Hydrogen Cations

4.6.1.1. H⁺ Ion. The naked proton “H⁺” exists only in the gas phase. In the condensed state, the proton is always solvated, thus no free proton is capable of existence. It is customary, however, as short hand notation to depict “H⁺” as the solvated proton.

4.6.1.2. H₃⁺ Ion. The H₃⁺ ion was discovered by Thompson in 1912 in hydrogen discharge studies. Actually, it was the first observed gaseous ion–molecule reaction product [Eq. (4.254)] and the reaction sequence was established in 1925 by Hogness and Lunn. Since then, extensive mass spectrometric studies of H₂, D₂, and their mixtures have been carried out in an effort to study thermodynamic and kinetic aspects of ion–molecule reactions of (H,D)₃⁺ cations.

\[ \text{H}_2^+ + \text{H}_2 \rightarrow \text{H}_3^+ + \text{H} \quad (4.254) \]

Despite numerous studies in the gas phase on H₃⁺, not much solution chemistry has been reported until the 1960s. Gillespie and Pez reported that according to their solubility, cryoscopic, and ¹H NMR spectroscopic measurements, HSO₃F–SbF₅–(Magic Acid)–SO₂ is not sufficiently strong to protonate a series of weak bases, including molecular hydrogen. Their investigation pertained, however, to observe H₃⁺ as a stable, detectable intermediate with a long life.

Olah, Shen, and Schlosberg were subsequently able to observe the hydrogen–deuterium exchange of molecular H₂ and D₂, respectively, with 1:1 HF–SbF₅ and HSO₃F–SbF₅ at room temperature. The facile formation of HD does indicate that protonation or deuteriation occurs, involving H₃⁺ at least as transition states in the kinetic exchange process. The H₃⁺ ion is the simplest two-electron three-center-bonded entity. The H₃⁺ ion has also been observed by IR spectroscopy.

4.6.2. Cations of Noble Gases

Reviews about the chemistry of noble gases including the cations of xenon and krypton are available.
A large number of \( \text{Xe}_{n}^{+} \) cations \((n \leq 30)\) have been detected by mass spectrometry,\(^{1048}\) and the \( \text{Xe}_{2}^{2+} \) ion was first generated in the solution phase in 1978.\(^{1049}\) Drews and Seppelt\(^{1050}\) were the first, however, to report the isolation and molecular structure of \( \text{Xe}_{2}^{2+}\text{Sb}_{4}F_{21}^{-} \) (365) [Eq. (4.255)]. In the crystals of the dark green compound, weak multiple contacts exist between xenon and fluorine atoms. The \( \text{Xe}/\text{Xe} \) bond is surprisingly long (3.087 Å) but much shorter than the theoretically predicted values (3.17–3.27 Å).

\[
\text{XeF}^+\text{Sb}_{2}F_{11}^- + \text{Xe} \xrightarrow{\text{HF-SbF}_5, -196 \text{ to } 0^\circ \text{C}} \text{Xe}_2^+\text{Sb}_{4}F_{21}^- \quad (4.255)
\]

The solution of \( \text{Xe}_{2}^{2+} \) has recently been shown to undergo a color change from green to dark blue upon increasing the xenon pressure.\(^{1051}\) Of the possible cationic species \((\text{Xe}_{n}^{m+}, n = 2–4; m = 1, 2)\), calculated vibrational spectra and energies agree well with those observed for \( \text{Xe}_{4}^{4+} \), but the presence of higher xenon aggregates \((\text{Xe}_{4}^{4+}/\text{Xe}_n)\) cannot be ruled out. According to calculations, the ion has a symmetric linear structure \((D_{\infty h}, \text{Xe}/\text{Xe} \text{ bond lengths } = 3.529 \text{ Å and } 3.190 \text{ Å}).

Both xenon and krypton are known to undergo ion–molecule reaction with \( \text{H}^+ \) to give the corresponding onium ions. The \( \text{XeH}^+ \) and \( \text{KrH}^+ \) ions are well-recognized in mass spectroscopic studies.\(^{1052–1060}\) and they have been also characterized by IR\(^{1061}\) and microwave spectroscopy.\(^{1062}\) The \( \text{Xe}_2\text{H}^+ \) cation has been observed in low-temperature matrices,\(^{1063}\) whereas \( \text{Xe}_2\text{H}^+_3 \) has been studied by \textit{ab initio} methods.\(^{1064}\) Homogeneous and mixed noble gas species \( \text{Ar}_2\text{H}^+, \text{KrH}^+, \text{Xe}_2\text{H}^+, \text{ArKrH}^+, \text{ArXeH}^+ \) have also been observed.\(^{1065}\) Even methylated xenon and krypton, \( \text{CH}_3\text{Xe}^+ \) and \( \text{CH}_3\text{Kr}^+ \), have been observed by Holtz and Beauchamp\(^{1066}\) in the gas phase. The carbon–inert gas atom bond strengths in these cations are estimated to be 43 ± 8 and 21 ± 15 kcal mol\(^{-1}\), respectively. The \( C-\text{Xe} \) bond strength in \( \text{CH}_3\text{Xe}^+ \) was determined by ion cyclotron resonance to be 55.2 ± 2.5 kcal mol\(^{-1}\).\(^{1067}\)

In solution chemistry too attempts have been made to protonate xenon to \( \text{XeH}^+ \) in the superacid media.\(^{150,1038}\) Evidence for the protonation comes from suppression of proton–deuterium exchange rates of deuterium gas in the presence of xenon in strong acid medium.\(^{342}\)

In 1989 the synthesis and isolation of the first compounds with stable \( \text{Xe–C} \) bond were reported by Naumann and Tyrra\(^{285}\) and Frohn and Jakobs\(^{1068}\) by the introduction of the organic group through nucleophilic substitution called xenodeborylation [Eq. (4.256)]. The boron as Lewis acid center polarizes the \( \text{Xe–F} \) bond and thereby allows it to overcome the low electrophilicity of the \( \text{Xe} \) center to form the fluoroaryl xenonium fluoroborates 366. When the reaction is carried out in anhydrous \( \text{HF} \), all \( \text{C}_6\text{F}_5 \) groups of the borane are transferred to xenon [Eq. (4.256)].\(^{1069}\)

\[
\text{XeF}_2 + (\text{C}_6\text{F}_5)_3\text{B} \rightarrow \text{C}_6\text{F}_5\text{Xe}^+\text{Y}^- \quad \text{MeCN, } 0^\circ \text{C}, \ Y = (\text{C}_6\text{F}_5)_3\text{BF} \\
\text{CH}_2\text{Cl}_2,-30^\circ \text{C}, \ Y = \text{C}_6\text{F}_5\text{BF}_3 \quad (4.256) \\
\text{HF}, -30^\circ \text{C}, \ Y = \text{BF}_4 \text{ and } \text{F(HF)}_n
\]
Frohn et al.\textsuperscript{1070} have obtained the X-ray structure of the acetonitrile complex of the salt C\textsubscript{6}F\textsubscript{5}Xe\textsuperscript{+}(C\textsubscript{6}F\textsubscript{5})\textsubscript{2}BF\textsubscript{2}. The Xe–C bond distance is 2.092 Å and the Xe–N contact is 2.681 Å. The \textsuperscript{129}Xe NMR spectrum contains a triplet at \( \delta \)\textsuperscript{129}Xe = 1956, and the coupling with the ortho F atoms (\( J_{Xe-F} = 68.8 \) Hz) indicates the presence of the Xe–C bond. The \textsuperscript{129}Xe NMR resonance (–1784.5) is strikingly high-field compared with that of XeF\textsubscript{2}, which is attributed to the solvation of the cation by acetonitrile. At the same time, the signals in the \textsuperscript{19}F NMR spectrum are shifted significantly downfield relative to the isoelectronic C\textsubscript{6}F\textsubscript{5}I molecule, indicating charge delocalization to the aromatic ring. Subsequently, the X-ray structure of \textbf{366} (\( Y = \text{AsF}_6 \)) prepared by metathesis from \textbf{366} [\( Y = (\text{C}_6\text{F}_5)_2\text{BF}_2 \)] was also reported.\textsuperscript{1071} In the crystal cell, there are two independent molecules. In each, one fluorine atom of the anion forms an almost linear but asymmetric C–Xe–F contact (C–Xe bond lengths = 2.079 and 2.082 Å, Xe–F distances = 2.714 and 2.672 Å, C–Xe–F angles = 170.5 and 174.2°). There are also additional Xe–Fe contacts. Schrobilgen, Frohn, and co-workers\textsuperscript{1072} have recently synthesized new examples of C\textsubscript{6}F\textsubscript{5}Xe\textsuperscript{+} salts with a range of weakly coordinating anions \( BY_4^- \) [\( Y = \text{CF}_3, \text{C}_6\text{F}_5, \text{CN}, \text{OTeF}_5 \)].

The xenodeborylation method has been extended to hydrogen-containing aryl compounds, in which the aryl group bears at least one electron-withdrawing substituent (F or CF\textsubscript{3}).\textsuperscript{1073,1074} The resulting salts, however, are unstable in CH\textsubscript{2}Cl\textsubscript{2}. When the synthesis is carried out in the presence of BF\textsubscript{3}·OMe\textsubscript{2}, in turn, stable tetrafluoroborates are isolated.\textsuperscript{1075–1077} Recently, Frohn et al.\textsuperscript{1078} have developed a more convenient route to xenonium salts by the use of aryldifluoroboranes generated in situ [Eq. (4.257)].

\[
\begin{align*}
\text{KArBF}_3 + \text{BF}_3 & \xrightarrow{\text{CH}_2\text{Cl}_2,-40 \text{ to } -50^\circ\text{C}} \text{ArBF}_2 \xrightarrow{\text{XeF}_2, \text{CH}_2\text{Cl}_2} \text{ArXe}^+\text{BF}_4^- \\
\text{Ar} & = \text{C}_6\text{F}_5, 2,3,4,5-\text{F}_4\text{C}_6\text{H}, 3,4,5-\text{F}_3\text{C}_6\text{H}_2, 3,5-\text{F}_2\text{C}_6\text{H}_3
\end{align*}
\]

(4.257)

Naumann et al.\textsuperscript{1079,1080} developed the xenodeprotonation method using the unique electrophilic Xe(II) reagent to generate arylxenononium triflates from highly deactivated benzene derivatives [Eq. (4.258)]. Stable derivatives were isolated in low yields (10–15%), whereas other products were observed by NMR spectroscopy. The cations and anions in the crystals of \([\text{Xe}(2,6-\text{F}_2\text{C}_6\text{H}_3))^{+}\text{TF}_2\text{O}^-\) are weakly coordinated through short Xe–O contacts.

\[
\begin{align*}
\text{XeF}_2 + \text{CF}_3\text{COOH} & \xrightarrow{\text{CCl}_3\text{F}, -40^\circ\text{C}} \text{CF}_3\text{CO}_2\text{XeO}_3\text{SCF}_3 \xrightarrow{\text{Ar}^-\text{H}, \text{CCl}_3\text{F}, -40^\circ\text{C}} \text{ArXe}^+\text{TF}_2\text{O}^- \\
\text{Ar} & = \text{C}_6\text{F}_5, \text{ClC}_6\text{H}_4, 1,3-\text{F}_2\text{C}_6\text{H}_3, 1,3,5-\text{F}_3\text{C}_6\text{H}_2, 1,3,5-\text{Cl}_3\text{C}_6\text{H}_2, \text{NO}_2\text{C}_6\text{H}_4, 1,3-(\text{NO}_2)_2\text{C}_6\text{H}_4, 1-\text{F},4-\text{NO}_2\text{C}_6\text{H}_3, 1-\text{F},4-\text{CF}_3\text{C}_6\text{H}_3, 1,3-(\text{CF}_3)_2\text{C}_6\text{H}_3
\end{align*}
\]

(4.258)
Fluorinated vinyl derivatives 367a and 368a have also been prepared by Frohn and Bardin,\textsuperscript{1081} and the synthesis of the partially fluorinated 367b and 368b and oxygenated compounds 369 and 370 was also reported.\textsuperscript{1082} They utilized the method described in Equation (4.257) for the synthesis of the first acyclic vinylxenon compound 371.\textsuperscript{1083} Alkynylxenonium salts have been obtained by Stang and co-workers\textsuperscript{1084} (372) and Frohn and Bardin\textsuperscript{1085,1086} (373).

Frohn et al.\textsuperscript{1087} have recently reported the first organoxenon(IV) compound [Eq. (4.259)]. The $^{129}$Xe resonance is significantly shielded compared to that of XeF$_4$ ($^{129}$Xe $\delta$ 1706.5 versus 316.9). The three substituents and the two nonbonding electron pairs of Xe predict a pseudo-trigonal–bipyramidal arrangement and a T-shaped molecular geometry.

\begin{equation}
C_6F_5BF_2 + \text{XeF}_4 \xrightarrow{\mathrm{CH}_2Cl_2, -55^\circ\mathrm{C}} F\text{Xe}^+\text{BF}_4^- \tag{4.259}
\end{equation}

The fluorides and oxyfluorides of xenon are well recognized.\textsuperscript{1088–1090} Most of the xenon fluorides and oxyfluorides react with Lewis acids to give the corresponding cations. The following cations have been prepared and characterized spectroscopically: XeF$^+$,\textsuperscript{1091} XeF$_3^+$,\textsuperscript{1092} XeF$_2^+$,\textsuperscript{1041} XeF$_5^+$,\textsuperscript{1041} Xe$_2$F$_{11}^+$,\textsuperscript{1093} XeOF$_3^+$,\textsuperscript{1092} and XeO$_2$F$^+$,\textsuperscript{1092,1094} and [FO$_2$XeF$_2$O$_2$F]$^+$.\textsuperscript{1094} XeF$^+$ salts have widely been used for oxyfluorination.\textsuperscript{73} The X-ray structure of XeF$^+$,\textsuperscript{1050,1095} XeF$_3^+$,\textsuperscript{1096–1098} XeF$_5^+$,\textsuperscript{1097} XeOF$_3^+$,\textsuperscript{1099} XeO$_2$F$^+$,\textsuperscript{1100} and [FO$_2$XeF$_2$O$_2$F]$^{+1100}$ has been determined. Cations containing the highly electronegative fluoro analog OTeF$_5$ ligand, such as XeOTeF$_5^+$,\textsuperscript{1101–1106} Xe$_2$(OTeF$_5$)$_3^+$,\textsuperscript{1104} O$_2$XeOTeF$_5^+$,\textsuperscript{1107} [F$_n$Xe(OTeF$_5$)$_3$–$n$]$^+$ and [OXeF$_n$(OTeF$_5$)$_3$–$n$]$^+$ ($n = 0–2)\textsuperscript{1107}$ have also been prepared and studied.
experimentally and theoretically. Additional examples are [F₅TeN(H) Xe]⁺AsF₆⁻, [CF₃C(OXeF)NH₂]⁺AsF₆⁻, and various adducts such as [RC≡NXeF]⁺AsF₆⁻. Recently, the XeO⁺ and XeOH⁺ ions have been observed in the gas phase, and the XeOO⁺ ion has been prepared and characterized in solid argon matrix.

Cations of Xe bonded to nitrogen are [XeN(SO₂F)₂]⁺MF⁻ (MF = AsF₆, Sb₃F₁₆), F[XeN(SO₂F)₂]⁺AsF₆⁻, [F₅TeN(H)Xe]⁺AsF₆⁻, [CF₃C(OXeF)NH₂]⁺AsF₆⁻, and various adducts such as [RC≡NXeF]⁺AsF₆⁻ (R = H, Me, Et, CH₂F, CF₃, C₂F₅, C₃F₇, C₆F₅), [F₃S≡NXeF]⁺AsF₆⁻. The anion of [F₅TeN(H)Xe]⁺AsF₆⁻ in the solid state forms a fluorine bridge with the Xe of the cation [F₅TeN(H)Xe]⁺ (F–Xe–N = 171.6°). The arrangement of the Xe, Te, and H atoms around the nitrogen is nearly tetrahedral. The salt [F₃S≡NXeF]⁺AsF₆⁻ synthesized by reacting XeF⁺AsF₆⁻ with N≡SF₃ was extensively characterized. Calculations predict a linear geometry of the cation; however, the actual geometry in the crystal state is nonlinear (Xe–N–S bond angle = 142.6°), which is attributed to close N–F contacts in the unit cell and crystal packing. Calculations also reveal a very weak Xe–N donor–acceptor interaction.

In contrast to the numerous examples discussed, only two chlorine-containing xenon cations are known. Seidel and Seppelt observed the formation of a blue solution in the reaction shown in Eq. (4.260) containing Cl₄⁺ formed by oxidation. Slow cooling of this solution resulted in the deposition of XeCl⁺SbF₁₁⁻ as orange crystals formed in the Cl/F exchange reaction. As predicted by ab initio calculations, the Xe–Cl bond in the XeCl⁺ cation corresponds to a Xe–Cl single bond (2.307 Å) and is much shorter than in any XeCl compounds. There is a cation–anion contact forming an almost linear Cl–Xe–F array with a contact distance of 2.628 Å.

Frohn and coworkers have obtained the unique chloronium cation which is the first unambiguously characterized xenon(II) chlorine compound [Eq. (4.261)]. There is no strong contact between cation 374 and the anion in the solid state. The two C–Xe–Cl contacts are linear (bond angles = 176.0 and 178.8°) with shorter C–Xe (2.111 and 2.116 Å) and longer Xe–Cl (2.784 and 2.847 Å) bond lengths. The Xe–Cl–Xe bond angle is 116.96°.

\[
\text{XeF}^+\text{SbF}_6^- + \text{SbCl}_5 \xrightarrow{\text{HF–SbF}_5} \text{XeCl}^+\text{SbF}_{11}^- \quad \text{(4.260)}
\]

\[
2\text{C}_6\text{F}_5\text{Xe}^+\text{AsF}_6^- \xrightarrow{\text{CH}_2\text{Cl}_2, -78^\circ\text{C}} \begin{array}{c} \text{C}_6\text{F}_5\text{Xe} \\ \text{Cl}^+\text{AsF}_6^- \\ + 6\text{Me}_3\text{SiF} + \text{AsCl}_3 + \text{Cl}_2 \end{array} \quad \text{(4.261)}
\]
Similarly to xenon fluorides, krypton fluorides give cations KrF$^+$ and Kr$_2$F$_3$$^+$ with Lewis acids. As mentioned earlier, cation salts Kr$_2$F$_3$$^+$SbF$_6^-$ and Kr$_2$F$_3$$^+$AsF$_6^-$ are capable of oxidizing bromine pentafluoride to BrF$_6^+$ cation. The crystal structure of both cations has been obtained. In the solid state, the KrF$^+$ ion has an interesting feature that is not observed for XeF$^+$ salts: there is a small, but significant deviation from linearity of the F–Kr–F moiety (175.4–177.9°). The KrO$_n^+$ ($n = 1, 2$) ion has been shown to be a stable species in the gas phase. Kohn and Frenking have calculated the structures and stabilities of He$_2$O$_2^+$, He$_2$N$_2^+$, and He$_2$C$_2^+$ dications, and Radom and co-workers found (ab initio studies at the MP4/6-311G** level) that the triheliomethyl trication (He$_3$C$_3^+$) and tetraheliomethane tetracation (He$_4$C$_4^+$) should behave experimentally observable. Olah, Prakash, and Rasul have found that both the $C_s$ symmetry structure of the helionitronium trication (HeNO$_2$$_3^+$) and the $C_{oeg}$ structure of helionitrosonium trication (HeNO$_3$$_3^+$) are minima on the potential energy surface (ab initio MP2/6-31G** level). In the trication HeNO$_2$$_3^+$, oxygen is strongly bonded to helium. Dissociation of the trication to NO$^+$ and OHe$_2^+$ is thermodynamically preferred by 183.1 kcal mol$^{-1}$, but dissociation has a kinetic barrier of 12.4 kcal mol$^{-1}$. Recent multireference configuration interaction (MRCI) studies have shown that the triplet state of $C_2v$ symmetry with He bonding to the N atom is the ground state for the helionitronium trication (HeNO$_2$$_3^+$).

CHAPTER 5

Superacid-Catalyzed Reactions

In discussing superacids as catalysts for chemical reactions, we will review both liquid (Magic Acid, fluoroantimonic acid, etc.) and solid (Nafion-H, etc.) acid-catalyzed reactions, but not those of conventional Friedel–Crafts-type catalysts. The latter reactions have been extensively reviewed elsewhere (see G. A. Olah, Friedel–Crafts Chemistry, Wiley, New York, 1972; G. A. Olah, ed., Friedel–Crafts and Related Reactions, Vols. I–IV, Wiley-Interscience, New York, 1963–1965).

As already mentioned and shown, considerable experimental and theoretical evidence has been collected over the last decades, which supports the idea of superelectrophilic activation, that is, protosolvation\(^1,2\) or de facto protonation of cationic intermediates.\(^3\)–\(^5\) Examples of superelectrophiles as highly reactive dicatic (doubly electron-deficient) and tricationic intermediates were discussed in Chapter 4.

The success of carbocation chemistry lies in the stabilization of carbocations in a medium of low nucleophilicity. Superelectrophiles, in turn, are reactive intermediates generated by further protonation (protosolvation). This second protonation increases electron deficiency, induces destabilization, and, consequently, results in a profound increase in reactivity. In particular, charge–charge repulsive interactions\(^6\) play a crucial role in the enhanced reactivity of dicatic and tricationic superelectrophilic intermediates. As various examples of acidity dependence studies show, without an appropriate acidity level, transformations may occur at much lower rate or even do not take place at all. In addition to numerous examples of superacid catalyzed reactions, various organic transformations, in which the involvement of superelectrophilic intermediates is invoked or superelectrophiles are de facto observed in the condensed state, are also included in this chapter.

5.1. CONVERSION OF SATURATED HYDROCARBONS

Solid and liquid acid-catalyzed hydrocarbon conversions involve by far the largest amount of catalysts and largest economic efforts in oil refining and chemical
Saturated hydrocarbons are the main components of natural gas and crude oil, which play presently an absolute key role in world economy as the number one source not only of energy but also of chemical feedstock covering our daily needs.

At the end of the 1800s, saturated hydrocarbons (paraffins) played only a minor role in industrial chemistry. They were mainly used as a source of paraffin wax as well as for heating and lighting oils. Aromatic compounds such as benzene, toluene, phenol, and naphthalene obtained from destructive distillation of coal were the main source of organic materials used in the preparation of dyestuffs, pharmaceutical products, and so on. Calcium carbide-based acetylene was the key starting material for the emerging synthetic organic industry. It was the ever-increasing demand for gasoline after the First World War that initiated study of isomerization and cracking reactions of petroleum fractions. After the Second World War, rapid economic expansion necessitated more and more abundant and cheap sources for chemicals and this resulted in the industry switching over to petroleum-based ethylene as the main source of chemical raw material. One of the major difficulties that had to be overcome is the low reactivity of some of the major components of the petroleum. The lower boiling components (up to 250°C) are mainly straight-chain saturated hydrocarbons or paraffins, which, as their name indicates (*parum affinis*: slight reactivity), have very little reactivity. Consequently, the lower paraffins were cracked to give olefins (mainly ethylene, propylene, and butenes). The straight-chain liquid hydrocarbons have also very low octane numbers, which make them less desirable as gasoline components. To transform these paraffins into useful components for gasoline and other chemical applications, they have to undergo diverse reactions such as isomerization, cracking, or alkylation. These reactions, which are used on a large scale in industrial processes, necessitate acidic catalysts (at temperatures around 100°C) or noble metal catalysts (at higher temperature, 200–500°C) capable of activating the strong covalent C–H or C–C bonds.10

Despite worldwide trends toward severe environmental legislation, the use of such acids as HF and H₂SO₄ is still in effect because of their high activity at low temperature. But simultaneously a huge effort has been and is still currently underway to develop solid or supported strong acids, which are easier to handle and to recycle. This trend is reflected by the impressive number of patents, special issues, and reviews devoted to this subject.11–16

The preparation of new solid acids, their characterization, mechanistic studies, and theoretical approaches to understand the fundamental aspects of acid-catalyzed hydrocarbon conversion constitute a very large fraction of the topics discussed in the last decade in all journals related to catalysis and physical chemistry. However, in contrast with liquid-acid-catalyzed activation processes, many fundamental questions concerning the initial step, the true nature of the reaction intermediates, and the number of active sites remain open for discussion. For this reason, the results obtained in liquid-superacid-catalyzed chemistry, which can be rationalized by classical reaction mechanisms, supported by the usual analytical tools of organic chemists, represent the fundamental basis to which scientist in the field refer.
Since the early 1960s, superacids are known to react with saturated hydrocarbons, even at temperatures much below 0°C. This discovery initiated extensive studies devoted to hydrocarbon conversions.

5.1.1. Sigma-Basicity: Reversible Protonation or Protolysis of C–H and C–C Bond

The fundamental step in acid-catalyzed hydrocarbon conversion processes is the formation of the intermediate carbocations. Whereas all studies involving isomerization, cracking, and alkylation reactions under acidic conditions (Scheme 5.1) agree that a trivalent carbocation (carbenium ion) is the key intermediate, the mode of their formation of this reactive species from the neutral hydrocarbon remained controversial for many years.

\[
\begin{align*}
R-H & \xrightarrow{\text{acid}} R^+ \\
\text{isomerization} & \\
\text{cracking} & \\
\text{alkylation–homologation} & \\
\end{align*}
\]

Scheme 5.1

Due to the unclear picture concerning the initial step in hydrocarbon conversion on solid acids, generally one of four pathways can be found in the literature: protolysis (1), hydride abstraction by an already existing carbenium ion (2), hydride abstraction by a Lewis acid (M) (3), and oxidation (4) (Scheme 5.2).

\[
\begin{align*}
\text{RH} + \text{"H"}^+ & \rightarrow \text{R}^+ + \text{H}_2 \quad (1) \\
\text{RH} + \text{R}^+ & \rightarrow \text{R}^+ + \text{RH} \quad (2) \\
\text{M} + \text{RH} & \rightarrow \text{R}^+ + \text{MH} \quad (3) \\
\text{RH} & \xrightarrow{-2 \text{ e}^-} \text{R}^+ + \text{"H"}^+ \quad (4)
\end{align*}
\]

Scheme 5.2

In 1946 Bloch, Pines, and Schmerling\(^{17}\) observed that \(n\)-butane (1) isomerizes to isobutane (2) under the influence of pure aluminum chloride only in the presence of HCl. They proposed that the ionization step takes place through initial protolysis of the alkane as evidenced by formation of minor amounts of hydrogen in the initial stage of the reaction [Eq. (5.1)].

\[
\begin{align*}
\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_3 + \text{HCl} & \xrightarrow{\text{AlCl}_3} \text{CH}_3\text{CH}^\cdot\text{CH}_2\text{CH}_3 \quad \text{AlCl}_4^- + \text{H}_2 \quad (5.1)
\end{align*}
\]

The first evidence of protonation of alkanes under superacid conditions has been reported by Olah and Lukas\(^{18}\) as well as by Hogeveen and co-workers.\(^{19,20}\)
When \( n \)-butane 1 or isobutane 2 was reacted with \( \text{HSO}_3\text{F-SbF}_5 \) (Magic Acid), tert-butyl cation 4 was formed exclusively [Eq. (5.2)] as evidenced by a sharp singlet at 4.5 ppm (from TMS) in the \( ^1\text{H} \) NMR spectrum. In excess Magic Acid, the stability of the ion is remarkable and the NMR spectrum of the solution remains unchanged even after having been heated to 110°C.

\[
\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_3 \xrightarrow{\text{HSO}_3\text{F-SbF}_5} (\text{CH}_3)_3\text{C}^+ \text{SbF}_5\text{FSO}_3^- + \text{H}_2 \xrightarrow{\text{RT}} (\text{CH}_3)_3\text{CH}^-  \\
\text{1} \quad 4 \quad 2
\]

It was also shown\(^{21}\) that the tert-butyl cation 4 undergoes degenerate carbon scrambling at higher temperatures (see Chapter 3). A lower limit of \( E_a \sim 30 \text{ kcal mol}^{-1} \) was estimated for the scrambling process, which could correspond to the energy difference between tert-butyl cation 4 and primary isobutyl cation 5 (the latter being partially delocalized).

\[
\text{H}_3\text{C} \quad \text{CH} \quad \text{CH}_2 \quad \text{H}_3\text{C} \\
5
\]

\( n \)-Pentane and isopentane are ionized under the same conditions to the tert-amyl cation. \( n \)-Hexane 6 and the branched \( C_6 \) isomers ionize in the same way to yield a mixture of the three tertiary hexyl ions [Eq. (5.3)] as shown by their \( ^1\text{H} \) NMR spectra.

\[
n\text{C}_6\text{H}_{14} \xrightarrow{\text{HSO}_3\text{F-SbF}_5} \text{+} + \text{+} + \text{+} \xrightarrow{\text{5.3}} \\
6
\]

Both methylcyclopentane and cyclohexane were found to give the methylcyclopentyl ion, which is stable at low temperature, in excess superacid.\(^ {22}\) When alkanes with seven or more carbon atoms were used, cleavage was observed with formation of the stable tert-butyl cation 4. Even paraffin wax (see Section 2.2.2.2 on Magic Acid) and polyethylene ultimately gave the tert-butyl cation 4 after complex fragmentation and ionization processes.

In compounds containing only primary hydrogen atoms such as neopentane 7 [Eq. (5.4)] and 2,2,3,3-tetramethylbutane, a carbon–carbon bond is broken rather than a carbon–hydrogen bond.\(^ {23}\)

\[
\text{CH}_3 \quad \text{CH}_3 \quad \text{+} \quad \text{H}^+ \quad \text{CH}_4 \quad \text{+} \quad (\text{CH}_3)_3\text{C}^+ \xrightarrow{\text{5.4}} \\
\text{7} \quad 4
\]
Results of protolytic reactions of hydrocarbons in superacid media were interpreted by Olah as indication for the general electrophilic reactivity of covalent C–H and C–C single bonds of alkanes and cycloalkanes. The reactivity is due to the \( \sigma \)-donor ability of a shared electron pair (of \( \sigma \)-bond) via two-electron, three-center bond formation. Consequently, the transition state of the reaction, is of three-center bound pentacoordinate carbonium ion nature [Eq. (5.5)].

\[
\begin{align*}
R - C - H & \xrightarrow{H^+} \left[ R - C \cdots H \right]^+ \rightarrow R_3C^+ + H_2 \\
\end{align*}
\]  

5.1.1.1. Deuterium–Hydrogen Exchange Studies. H/D exchange between alkanes and strong or superacids have proven very useful for mechanistic investigations. Already in the early 1970s, monodeuteromethane was reported to undergo H–D exchange without detectable side reactions in the HF–SbF\(_5\) system\(^{24}\) [Eq. (5.6)]. \( d_{12} \)-Neopentane, when treated with Magic Acid, was also reported to undergo H–D exchange before cleavage.\(^{25}\)

\[
\begin{align*}
HF - SbF_5 + CH_3D & \longrightarrow \left[ H_3C \cdots H \right]^+ \rightarrow CH_4 + DF - SbF_5
\end{align*}
\]  

Based on the demonstration of H–D exchange of molecular hydrogen (and deuterium) in superacid solutions, Olah et al.\(^{26}\) suggested that these reactions go through trigonal isotopic \( H_3^+ \) ions (8, 9) in accordance with theoretical calculations and IR studies.\(^{27}\)

\[
\begin{align*}
\begin{array}{c}
\text{H}^+ \\
\text{D}^+
\end{array} & \quad \begin{array}{c}
\text{H}^+ \\
\text{D}^+
\end{array}
\end{align*}
\]  

Consequently, the reverse reaction of protolytic ionization of hydrocarbons to carbenium ions—that is, the reduction of carbenium ion by molecular hydrogen\(^{28,29}\) — can be considered as alkylation of \( H_2 \) by the electrophilic carbenium ion through a pentacoordinate carbonium ion. Indeed, Hogeveen and Bickel have experimentally proved this point by reacting stable alkyl cations in superacids with molecular hydrogen [Eq. (5.7)].

\[
\begin{align*}
R_3C^+ + H_2 & \longrightarrow \left[ R_3C \cdots H \right]^+ \rightarrow R_3CH + H^+
\end{align*}
\]
However, due to competitive reaction pathways the reaction of small alkanes yields a quite complex product distribution (Schemes 5.2 and 5.3). Especially hydride transfer to the initially formed carbenium ions [reactions (2) and (3) in Scheme 5.2] makes it difficult to study the initial steps.

$$\begin{align*}
R^+ &+ R'^+ + 2 \text{CO} \rightarrow \text{RCO}^+ + R'\text{CO}^+ \\
\text{Scheme 5.3}
\end{align*}$$

However, if the reactions are run in the presence of carbon monoxide the initially formed carbenium ions are trapped as oxocarbenium ions, which do not initiate hydride abstraction [Eq. (5.8)].

$$R^+ + R'^+ + 2 \text{CO} \rightarrow \text{RCO}^+ + R'\text{CO}^+$$

By using this technique, Sommer and his group reinvestigated the H–D exchange reaction occurring between small alkanes and deuteriated superacids and showed that the reaction depended not only on the structure of the alkane but also very much on the superacid system.\(^{30,31}\)

**Methane.** Methane is abundant on earth. It is the major component of natural gas\(^8\) and is produced on short time scale by biological conversion of biomass.\(^{32}\) During the last decades much effort has been expended to the challenge of converting methane into useful products.\(^{33–38}\) One of the approaches is the electrophilic activation, which relies on the \(\sigma\)-basicity of the C–H bond—that is, its ability to react with strong electrophiles.\(^{39}\) In liquid superacids, Hogeveen and co-workers\(^{24,40}\) and Olah and co-workers\(^{23,25}\) have observed protium/deuterium exchange with methane and the methonium ion was suggested as an intermediate or transition state.

The methonium ion (CH\(_5^+\)) was first discovered in the mass spectrometer.\(^{41,42}\) A number of theoretical studies have shown its shallow potential energy surface\(^{43–47}\) (see also Section 3.5.1.1).

The eclipsed \(C_s\) conformer [\(C_s(e)\), Figure 5.1] is now accepted as being the lowest on the potential energy surface, although the barriers for rearrangements are extremely small. The barrier for methyl rotation to a staggered \(C_s\) conformation [\(C_s(s)\)] is about 0.1 kcal mol\(^{-1}\), and the exchange between two eclipsed \(C_s\) structures via a flip-transition state with \(C_{2v}\) symmetry is about 0.8 kcal mol\(^{-1}\). Addition of zero-point energy suggests that the energy difference is almost negligible.\(^{43}\) A recent high-resolution infrared spectrum in the gas phase seems to confirm that the parent alkonium ion CH\(_5^+\) is highly fluxional and that its structure is not described by a single nuclear configuration, although any assignment of peaks was not possible.\(^{48}\)
Methane and ethane, the weakest σ-bases, which are extremely difficult to ionize, will exchange hydrogens without side reaction in any acid having an $H_0$ value of −12 or below.

Methane is slightly soluble in HF–SbF$_5$ even at atmospheric pressure (0.005 M), which facilitates direct kinetic studies by NMR. Thus the transition states for methane activation in this medium have been studied experimentally by Ahlberg et al.$^{49}$ The first-order rate constants [Eqs. (5.9) and (5.10)], determined experimentally on the basis of $^2$H-decoupled 600-MHz $^1$H NMR time-dependent spectra (Figure 5.2), are on the order of $3.2 \times 10^{-4}$ s$^{-1}$ at $-20^\circ$C and show a secondary kinetic isotope effect (SKIE) of 1 ± 0.02.

![Figure 5.1. Calculated conformations of the methonium ion CH$_5^+$.](image)

By using the reagent pairs $^{13}$CH$_4$/12CH$_3$D and $^{13}$CH$_4$/12CH$_3$D$_2$ as starting materials, the first-order rate constants of all isotopologs were obtained and the secondary kinetic isotope effects were estimated to be around 1.00 ± 0.05. Because these results were surprising in view of the expected dramatic structural change in going from methane to the presumed methonium ion-like activated complex, DFT and $ab$ initio methods were used to optimize the structures and energies of the intermediates and transition states at various levels of theory. Protonation of methane by H$_2$F$^+$ to yield the strongly HF-hydrogen-bonded CH$_5^+$ ion 10 was found to be barrierless and lowered the potential energy by 29.0 kcal mol$^{-1}$. The activated complex 11 for hydrogen exchange showed a potential energy of only 1.9 kcal mol$^{-1}$
higher than 1, the exchange taking place in the complex. The methonium ion structure in 10 and 11 is closely similar to the $C_8$ structure in CH$_5^+$. 

Only the unsolvated superacid H$_2$F$^+$ was found to be strong enough to protonate methane to yield the methonium ion solvated by HF as a potential energy minimum. Similar calculations at the B3LYP/6-31++G**+RECP (SB) level have been performed by Mota and colleagues$^{50}$ using the H$_2$F$^+$Sb$_2$F$_{11}^-$ cluster as an electrophile to mimic the liquid superacid HF–SbF$_5$ and C$_1$–C$_4$ alkanes.
As methane is also slightly soluble in Magic Acid, the hydrogen exchange rate between methane and a series of DSO$_3$F–SbF$_5$ superacids could be measured by in situ $^2$H-decoupled $^1$H NMR spectroscopy (Figure 5.3).$^{51}$ The rates of exchange, much lower than in HF–SbF$_5$, showed a strong dependence on antimony pentfluoride concentration, with the free energy of activation $\Delta G^{\ddagger}_{30^\circ C}$ decreasing from 23 to 20 kcal mol$^{-1}$ over the range of concentration 19 to 49 mol% SbF$_5$. The constant free enthalpy of activation $\Delta H^{\ddagger}$ (about 15.5 kcal mol$^{-1}$) and the decreasing entropy of activation $\Delta S^{\ddagger}$ seem to indicate that an increase in acidity of the superacid system does not substantially change the nature of the transition state but rather its solvation. If the rates of exchange were directly related to acidity, the activation energy measured in the temperature range of –25$^\circ$C to +75$^\circ$C appeared to be constant, which would indicate that not the nature but only the concentration of the protonating species was changing when the amount of SbF$_5$ was increasing in order to increase the acidity. No exchange was observed when pure HSO$_3$F was used in the same temperature range.

At temperatures above 270°C, H–D exchange occurs even in D$_2$SO$_4$.$^{52}$ Above 300°C, however, oxidation to CO takes place, which is then further oxidized to CO$_2$ with the formation of SO$_2$ and water [Eqs. (5.13) and (5.14)].

$$\text{CH}_4 + 3 \text{H}_2\text{SO}_4 \rightarrow \text{CO} + 3 \text{SO}_2 + 5 \text{H}_2\text{O} \quad (5.13)$$

$$\text{CO} + \text{H}_2\text{SO}_4 \rightarrow \text{CO}_2 + \text{SO}_2 + \text{H}_2\text{O} \quad (5.14)$$
**Small Alkanes with More than Two Carbon Atoms.** Whereas methane and ethane show a very similar behavior towards superacidic media, alkanes with more than two carbon atoms undergo a more complex reaction scheme in which C–H and C–C bond cleavage compete with reversible protonation. In order to follow the initial steps, it is very useful to run the reaction in presence of carbon monoxide, which reacts rapidly with the initially formed carbenium ions yielding stable oxocarbenium ions unable to activate alkanes by hydride transfer.\(^5\)

When isobutane (2) is contacted with HF–SbF\(_5\) at \(-10^\circ\)C in the presence of carbon monoxide, analysis of the reaction products both from the gas phase and from the liquid phase can be rationalized by the two pathways described in Scheme 5.4.\(^3\)\(^0\)\(^5\)\(^4\)\(^5\)\(^5\)

The main pathway for ionization as expected is the protolytic cleavage of the tertiary C–H bond producing stoichiometric amounts of tert-butyl cation and hydrogen. The tert-butyl ion is converted into ethyl pivalate (12) after reaction with CO and neutralization of the superacid with ethanol–bicarbonate mixture. The minor pathway is C–C bond cleavage resulting in the formation of ethyl isobutyrate (13). The fact that in earlier work the purely protolytic pathway was questioned\(^2\)\(^3\) has now been explained on the basis of the composition of the HF–SbF\(_5\) system: When the concentration of SbF\(_5\) exceeds 20\% of HF, a small and increasing amount of uncomplexed SbF\(_5\) is present, which participates in the activation by an oxidative process (\textit{vide infra}).\(^5\)\(^6\)

The protolytic activation of the alkane is, however, only the apparent part of the reaction as long as the alkane or the acid is not isotopically labeled. When HF is replaced by DF and the isobutane–CO mixture is bubbled through the DF–SbF\(_5\) acid (6:1 molar ratio) at \(-10^\circ\)C, the apparent conversion based on ester or H\(_2\) formation is only 4\% but the \(^1\)H/\(^2\)H NMR analysis of the apparently unreacted isobutane (96\%) shows extensive H–D exchange (18 atom\% in the tertiary position and 9 atom\% at each primary position).\(^3\)\(^0\) The most plausible rationalization of hydrogen exchange is via the formation of carbonium ions (here pentacoordinate transition states or intermediates) as described in Eq. (5.15).

![Scheme 5.4](image-url)
By selective labeling experiments, it has been shown that, in contrast with \( \text{CH}_5^+ \), the proton scrambling does not occur in the iso\( \text{C}_4\text{H}_{11}^+ \) and \( \text{C}_3\text{H}_9^+ \) species. Rather, the exchange takes place between the alkane and the acid and not between the isotopolog structures of the iso\( \text{C}_4\text{H}_{11-}X\text{D}_x^+ \) and \( \text{C}_3\text{H}_9-\text{D}_x^+ \) species\(^{57}\) [Eqs. (5.16) and (5.17)].

\[

\end{align*}
\]

(5.17)

Under similar experimental conditions, propane is slightly ionized (2% conversion) but extensively deuteriated when bubbled through DF–SbF\(_5\) in the presence of CO (12 atom% in the primary position and 17 atom% in the secondary position). Skeletal rearrangement in protonated propane via carbonium-ion-type intermediates has been suggested several times based on results obtained with zeolites.\(^{58,59}\) This type of rearrangement could be excluded as \(^{13}\text{C}\)-labeled propane, extensively deuteriated in DF–SbF\(_5\), showed no \(^{13}\text{C}\) label scrambling.\(^{60}\)

Isopentane is the smallest alkane in the series, having primary, secondary, and tertiary hydrogens. Under similar conditions as propane and isobutane, isopentane was partially ionized in DF–SbF\(_5\) at \(-10^\circ\text{C}\) (10% conversion); the recovered 90% of alkane showed extensive deuterium/proton exchange (12 atom% of the primary, 16 atom% of the secondary, 19 atom% of the tertiary hydrogens were exchanged as expected in accord with their relative \(\sigma\)-basicity).\(^{61}\)

From these experiments, some general conclusions can be drawn concerning the behavior of small alkanes in the strongest HF–SbF\(_5\) system. (1) The reversible protonation of the alkanes (i) is very fast in comparison with the ionization step; (ii) it takes place on all \(\sigma\)-bonds independently of the subsequent reactivity of the alkane; (iii) it involves carbonium ions (transition states), which do not undergo molecular rearrangements. (2) Protonation of an alkane is a typical acid–base reaction and carbon monoxide has no effect on this step.

\textit{The Oxidative Pathway.} For a long time, one of the difficulties in understanding the mechanism of the superacid-catalyzed transformations of alkanes was that no
A stoichiometric amount of hydrogen gas evolution was observed from the reaction mixture. This led to a controversy, which was only solved in the early 1990s.

One mechanism that was proposed involves direct hydride abstraction by the Lewis acid\(^{62}\) [Eq. (5.18)].

\[
\text{RH} + 2 \text{SbF}_5 \rightarrow \text{R}^+ \text{SbF}_6^- + \text{SbF}_3 + \text{HF} \quad (5.18)
\]

Olah, however, pointed out that if \(\text{SbF}_5\) would abstract \(\text{H}^-\), it would need to form \(\text{SbF}_3\text{H}^-\) ion involving an extremely weak \(\text{Sb}—\text{H}\) bond compared to the strong \(\text{C}—\text{H}\) bond being broken.\(^{63}\) Calculations based on thermodynamics\(^{64}\) also seemed to indicate that the direct oxidation of alkanes by \(\text{SbF}_5\) was not feasible. Hydrogen is generally assumed to be partially consumed in the reduction of one of the superacid components [Eqs. (5.19) and (5.20)].

\[
\begin{align*}
2 \text{HSO}_3\text{F} + \text{H}_2 & \rightarrow \text{SO}_2 + \text{H}_3\text{O}^+ + \text{HF} + \text{SO}_3\text{F}^- \quad \Delta H = -49 \text{ kcal mol}^{-1} \quad (5.19) \\
\text{SbF}_5 + \text{H}_2 & \rightarrow \text{SbF}_3 + 2 \text{HF} \quad \Delta H = -33 \text{ kcal mol}^{-1} \quad (5.20)
\end{align*}
\]

It could, however, be shown\(^{30}\) that the amounts of hydrogen and ester obtained in the presence of CO from isobutane in HF–\(\text{SbF}_5\) are stoichiometric only as long as the \(\text{SbF}_5\) concentration is lower than 20%. For higher concentrations the ester production increases steadily whereas hydrogen formation decreases. Competition between ionization and exchange is described in Scheme 5.5.
Figure 5.4. Isobutane conversion based on ethyl pivalate production (□) compared with hydrogen production (○) (60 min time-on-stream).\textsuperscript{30}

An increasing amount of esters is accompanied by a decreasing amount of \( \text{H}_2 \) concomitant with reduction of \( \text{SbF}_5 \) to \( \text{SbF}_3 \) (Figure 5.4). The H–D exchange on tertiary and primary hydrogens as a function of the concentration of \( \text{SbF}_5 \) is shown in Figure 5.5.

The same phenomenon was observed\textsuperscript{61} with propane (Figure 5.6) and isopentane (Figure 5.7): above 20 mol\% of \( \text{SbF}_5 \), reversible protonation and protolytic ionization decrease rapidly whereas the conversion of the alkane with concomitant reduction of \( \text{SbF}_5 \) increases. H–D exchange data observed in small alkanes are collected in Table 5.1.

The direct reduction of \( \text{SbF}_5 \) in the absence of hydrocarbons by molecular hydrogen necessitates, however, more forcing conditions (50 atm, high temperature), which suggests that the protolytic ionization of alkanes proceeds probably via solvation of the protonated alkane by \( \text{SbF}_5 \) and concurrent ionization–reduction.\textsuperscript{63} That \( \text{SbF}_5 \) could be reduced by alkanes even in the absence of protons was demonstrated by Culmann and Sommer\textsuperscript{56} who showed that \( \text{SbF}_5 \) reacts with isobutane at 0\textdegree\ in the presence of a proton trap according to Eq. (5.21).

\[
\begin{align*}
\text{CH}_3\text{CH}_3 & + \text{O}^\cdot\text{C} - \text{CH}_3 + \text{H}_2\text{C} - \text{CH}_3 \rightarrow \text{CH}_3 - \text{C} - \text{CH}_3 + \text{H}_2\text{C} - \text{CH}_3 + \text{SbF}_3 + \text{F}^- \\
\end{align*}
\]

Figure 5.7. Isopentane conversion compared to hydrogen production.\textsuperscript{61}
This direct oxidation generates itself a proton and is probably only a minor pathway under superacidic condition where, in the absence of the proton trap, protolysis of the C—H and C—C bond occurs very rapidly. The mechanism is most probably of electron transfer nature as suggested in Eq. (5.22) and (5.23)

\]

**Small Alkanes with More than Two Carbon Atoms in Weaker Superacid Systems.** As already observed for methane (*vide supra*), with decreasing acidity it becomes more and more difficult to protonate reversibly C—H bonds. Nevertheless, when alkanes with more than two carbon atoms are used as starting material, carbenium ions are generated by competitive protolytic and oxidative processes. Depending on the strength of the superacid system, proton exchange can take place by two competitive reactions: (i) directly via reversible protonation and (ii) via deprotonation of the carbenium ion and reprotonation of the alkene.

Whereas the importance of the exchange mechanism via route (i) is rapidly decreasing with decreasing acidity, route (ii) is facilitated by the increasing basicity of the superacid counterion.

For this reason when Magic Acid (HSO\(_3\)F–SbF\(_5\), 1:1 molar ratio) is used under the same experimental conditions as above at room temperature, isobutane undergoes very slow ionization and the formation of the tert-butyl ion can be monitored. However, recovered isobutane shows no exchange because the reversible protonation via carbonium ion transition state does not take place and because the tert-butyl ion, stable in this solution at room temperature, does not deprotonate.

When still weaker superacids are used, such as HSO\(_3\)F (\(H_0 = -15\)) or CF\(_3\)SO\(_3\)H (\(H_0 = -14\)), linear alkanes do not react at room temperature, but branched alkanes are ionized via an oxidative process involving the reactive tertiary C—H bond. The tertiary cations that are generated undergo reversible deprotonation to alkenes that are reprotonated. This process ends when hydride transfer occurs from unreacted isoalkane; but, when deuteriated acids are used, it leads to isoalkanes extensively and regioselectively deuteriated on the carbons vicinal to the branching carbon. This exchange process is similar to the one observed by Otvos et al.\(^6^6\) in the early 1950s while studying the deuteriation of isobutane in D\(_2\)SO\(_4\) as described in Scheme 5.6.

Because the reaction is catalytic in tert-butyl cation and the deprotonation/reprotonation steps are very fast, extensive regioselective deuteriation of the isoalkane is observed at room temperature as shown by GC–MS analysis. The absence of mass 68 (\(d_{10}\)-isobutane) and the presence of mass 64 due to SO\(_2\) formation in the oxidative process are typical features in accord with the oxidative activation of the alkane and the Markovnikov-type addition of deuterons on the intermediate isobutylene (14). However, the exchange process does not take place in the presence of carbon monoxide, which traps the tert-butyl cation and prevents deprotonation (Scheme 5.7).
Alkanes and Strong Solid Acids. Since the early reports by Nenizetscu and Dragăn\textsuperscript{67} on alkane isomerization on wet aluminum chloride in 1933, all mechanistic studies have led to a general agreement on the carbenium-ion-type nature of the reaction intermediates involved in acid-catalyzed hydrocarbon conversions. In contrast with this statement, the nature of the initial step is still under discussion and a variety of suggestions can be found in the literature among which direct protolysis of C–C bonds, protonation of alkenes present as traces, and oxidative activation are the most often quoted.\textsuperscript{54,55}

Solid acids are generally oxides containing various OH groups, which may function as proton donors. The deuteriation of these OH groups allows mechanistic isotope tracer studies. Monitoring the appearance and localization of the isotope in the alkane activated by the solid acids will provide interesting information on the reaction mechanism. H–D exchange of the OH groups occurs readily at moderate temperatures below 200°C when the solid is exposed to D\textsubscript{2}O or at higher temperatures (500°C) in the presence of D\textsubscript{2}.

When isoalkanes are contacted with D\textsubscript{2}O-exchanged solid acids such as zeolites, sulfated zirconias, or heteropoly acids, proton–deuterium exchange takes place slowly even at room temperature; but above 100°C the catalysts are rapidly depleted of their deuterons, which are recovered in the alkane.\textsuperscript{54,55} This exchange process is
regioselective because only hydrogens vicinal to the branched carbon are exchanged in accord with a mechanism very similar to the one observed in $\text{H}_2\text{SO}_4$ and in weak acids (Scheme 5.8).

Linear alkanes, which are known to be less reactive, also undergo H–D exchange by the same mechanistic scheme at slower rates at and above 150°C.54,55 This exchange reaction occurs in a very clean way because no side products from cracking and isomerization are observed. The cations that are adsorbed on the surface are prone to deprotonation, but the alkenes that are formed are rapidly reprotonated before substantial oligomerization can take place.

The occurrence of carbenium ions as reaction intermediates is strongly supported by the observation that the isotopic exchange can be totally suppressed in the presence of carbon monoxide.68 Furthermore, trapping of the intermediate carbenium ions by CO and water has been observed by insitu NMR spectroscopy when isobutane, water, and CO reacted on HZSM-5 zeolite to form pivalic acid.69,70 Regarding the small conversion, only a limited number of acid sites are suggested to be strong enough for the initial protolytic activation to take place.

Methane does not react with $\text{D}_2\text{O}$-exchanged solid acids at temperatures below 400°C. The H–D exchange has, however, been observed on sulfated zirconia (SZ) at 400°C.71 When the stronger acid SZA3 (sulfated zirconia doped with 3% Al$_2$O$_3$) is used,72 the exchange rates are substantially higher.71 In the presence of D$_2$O-exchanged zeolites, the H–D exchange process can only be measured at temperatures as high as 500°C or higher.73

**Theoretical Approaches.** Computer modeling is an increasingly fruitful tool in catalysis, and several research groups have attempted to rationalize high carbon conversion over zeolites from a theoretical point of view. The main problem to be
solved is the choice of a model (generally a small cluster) representative of the zeolite framework.

Both the carbenium ion and carbonium ion transition states have been investigated. In the presence of the oxygen lone pairs, it is clear that the most stable reaction intermediates will not be free carbenium ion but surface alkoxy groups. The generation of these alkoxy species from alkenes has been demonstrated by Haw et al. The structure of the transition state of the H–D exchange process in methane has been calculated by van Santen and Kramer to be symmetrical with essentially covalent bond sharing character (Figure 5.8).

By modifying the proton affinity, the authors could demonstrate the dependence of the exchange rate on the proton affinity of the zeolite cluster, relating the activity of the catalyst with its acidity. The activity of the catalyst was found to be determined by the acidity differences between the proton donating and proton accepting oxygen sites. The calculated energy of activation is close to the experimentally determined values of approximately 33.5 kcal mol$^{-1}$ with an uncertainty of 5 kcal mol$^{-1}$. Restudying the mechanism of hydrogen exchange between methane and H-USY and replacing the bare cluster by an accurate ab initio embedded cluster, including the Madelung potential, Vollmer and Truong found that the transition state had carbonium-like characteristics from both geometric and electron density considerations. Using the CCSD(T)/6-31G(d,p) level of theory including zero-point energy and tunneling, the activation energy was predicted to be 30 $\pm$ 1 kcal mol$^{-1}$ and 34 $\pm$ 1 kcal mol$^{-1}$ for hydrogen exchange from two different binding sites.

It is interesting to compare this transition state in the solid with the one calculated from the HF–SbF$_5$ system. In the liquid superacid, the ionic character is very strong and it is easier to connect the reactivity with the unusual activity of the proton even when solvated by the HF solvent. In contrast, on the solid the theoretical calculated transition state is further away from the carbonium ion type and in line with the much higher temperatures needed to activate the alkane with weaker acids.

**Figure 5.8.** Calculated transition state geometry for H–D exchange between a zeolite cluster and methane.
5.1.2. Electrochemical Oxidation in Strong Acids

The protolytic oxidation of alkanes is also strongly supported by electrochemical studies. In 1973, Fleischmann, Plechter, and co-workers\textsuperscript{78} showed that the anodic oxidation potential of several alkanes in HSO\textsubscript{3}F was dependent on the proton donor ability of the medium. This acidity dependence shows that there is a rapid protonation equilibrium before the electron transfer step and it is the protonated alkane that undergoes oxidation (Scheme 5.9).

\[
\text{RH} \rightarrow \text{RSO}_3^+ \rightarrow \text{R}^+ + \text{H}^+ + \text{SO}_3^- \quad \text{(Eq. (5.2))}
\]

Scheme 5.9

The electrochemical oxidation of lower alkanes in the HF solvent system has been investigated by Devynck and co-workers\textsuperscript{79} over the entire pH range. Classical and cyclic voltammetry show that the oxidation process depends largely on the acidity level. Isopentane (15, 2-methylbutane, 2MeBuH), for example, undergoes two-electron oxidation in HF–SbF\textsubscript{5} and HF–TaF\textsubscript{5} solutions\textsuperscript{80} [Eq. (5.24)].

\[
\begin{align*}
2\text{MeBuH} & \rightarrow 2\text{MeBu}^+ + \text{H}^+ \\
\text{(5.24)}
\end{align*}
\]

In the higher-acidity region, the intensity–potential curve shows two peaks (at 0.9 V and 1.7 V, respectively, versus the Ag/Ag\textsuperscript{+} system). The first peak corresponds to the oxidation of the protonated alkane and the second the oxidation of the alkane itself.

The chemical oxidation process in the acid solution [Eq. (5.25)] can be considered as a sum of two electrochemical reactions [Eqs. (5.26) and (5.27)].

\[
\begin{align*}
\text{RH} + \text{H}^+ & \rightleftharpoons \text{R}^+ + \text{H}_2 \\
\text{(5.25)}
\end{align*}
\]

\[
\begin{align*}
2\text{H}^+ + 2\text{e}^- & \rightleftharpoons \text{H}_2 \quad (E^0_{\text{H}^+/\text{H}_2}) \\
\text{(5.26)}
\end{align*}
\]

\[
\begin{align*}
\text{RH} & \rightleftharpoons \text{R}^+ + \text{H}^+ + 2\text{e}^- \quad (E^0_{\text{R}^+/\text{RH}}) \\
\text{(5.27)}
\end{align*}
\]

The chemical equilibrium [Eq. (5.25)] is characterized by the constant \( K_1 \) [Eq. (5.28)]. With the experimental conditions set to control \( p_{\text{H}_2} \), the acidity level and \( \text{R}^+ \) concentration, \([\text{RH}]\) can be evaluated from voltammetric results and \( K_1 \) can be determined.

\[
K_1 = \frac{[\text{R}^+][p_{\text{H}_2}]}{[\text{RH}][\text{H}^+]} \quad \text{and} \quad R_A = \frac{[\text{R}^+][\text{H}^+]}{[\text{RH}]} = \frac{K_1}{p_{\text{H}_2}} \cdot [\text{H}^+] \quad \text{(5.28)}
\]

However, when log \( R_A \) is plotted as a function of pH, the authors noticed that in the case of 2MeBuH below pH = 1.25, the ratio becomes pH-independent (Figure 5.9).
Thus, at a higher acidity level, another equilibrium must be taken into account, which is the protonation of the alkane [Eq. (5.28)] with constant \( K_2 \) [Eq. (5.30)], and the oxidation reaction becomes pH-independent [Eq. (5.31)].

\[
\text{RH} + \text{H}^+ \rightleftharpoons \text{RH}_2^+ \tag{5.29}
\]

\[
K_2 = \frac{[\text{RH}_2^+]}{[\text{RH}][\text{H}^+]} \tag{5.30}
\]

\[
\text{RH}_2^+ \rightarrow \text{R}^+ + \text{H}_2 \tag{5.31}
\]

The acidity level at point A is representative of the basicity of the hydrocarbon: If \( K_A \) is the acidity constant of the protonated alkane, then \( \text{pH}_A = \text{p}K_A \). On the other hand, as the redox reactions [Eqs. 5.26 and 5.27] are combined in Eq. 5.25, the equilibrium constant \( K_1 \) is related to the standard potentials of redox couples \( \text{R}^+/\text{RH} \) and \( \text{H}^+/\text{H}_2 \) according to Eq. (5.32).

\[
\frac{2.3RT}{2F} \ln K_1 = E^0_{\text{H}^+/\text{H}_2} - E^0_{\text{R}^+/\text{RH}} \tag{5.32}
\]

Because \( K_1 \) can be determined experimentally and the oxidation potential of \( \text{H}^+/\text{H}_2 \) is known in the acidity range, oxidation potential can be calculated. This allowed the
authors to plot the B–D part of the potential–acidity diagram versus the H\(^+\)/H\(_2\) system as shown in Figure 5.10 for isopentane (15, 2MeBuH). The diagram shows that oxidation of the alkane (2MeBuH) by H\(^+\) gives the carbocation only at pH values below 5.7. In the stronger acids (pH < pH\(_A\)), it is the protonated alkane which is oxidized. At pH values higher than 5.7, oxidation of isopentane gives the alkane radical that dimerizes [Eqs. (5.33) and 5.34] or is oxidized in a pH-independent process [Eq. 5.35].

\[
\begin{align*}
2\text{MeBuH} & \rightarrow -e \rightarrow 2\text{MeBuH}^{++} \rightarrow 2\text{MeBu}^+ + H^+ \quad (5.33) \\
2\text{MeBu}^+ & \rightarrow (2\text{MeBu})_2^+ \quad (5.34) \\
2\text{MeBu}^+ & \rightarrow -e \rightarrow 2\text{MeBu}^+ \quad (5.35)
\end{align*}
\]

An interesting point is the intersection point \(R\) at which crossover of the H\(^+\)/H\(_2\) and the R\(^+\)/RH systems occurs. From this acidity level onwards, RH is oxidized spontaneously into R\(^+\).

This potential–acidity diagram (Pourbaix’s type) has been determined for a large series of alkanes.\(^{79}\) All of these results indicate two types of oxidation mechanism of the C–H bond: (i) oxidation of alkanes into carbenium ion at high acidity levels and (ii) oxidation of alkanes into radicals at low acidity levels.

Using isopentane 15 as a reference alkane, the authors calculated the Gibbs free energy between the redox couples of various alkanes and the 2MeBuH/2MeBu\(^+\) couple. This leads to the standard potential of the alkane redox couples in HF
Table 5.2. Standard Potential of Redox Couples of Alkanes in HF (at $H_0 \sim -22.1$) and Acidity Levels of Oxidation ($pH_R$ in HF).^{79}

(at $H_0 \sim -22.1$) (Table 5.2). The position of the redox couple $R^+/RH$ versus $H^+/H_2$ system leads to the determination of the oxidation pH or acidity level at which reaction in Eq. (5.31) is quantitative.

These results are in agreement with the alkane behavior in superacid media and indicate the ease of oxidation of tertiary alkanes. However, high acidity levels are necessary for the oxidation of alkanes possessing only primary C–H bonds.

Once the alkane has been partly converted into the corresponding carbenium ion, the carbenium ion may undergo various reactions following (a) intramolecular routes such as skeletal rearrangement [Eq. (5.36)] and fragmentation [Eq. (5.37)] or (b) intermolecular routes such as hydride transfer [Eq. (5.38)] and alkylation of another alkane molecule [Eq. (5.39)]. The specificity of some of these reactions will be discussed in the following sections.

\[
\begin{align*}
CH_3^+ & \rightleftharpoons CH_3 + CH_3^+ \\
CH_3^+ & \rightleftharpoons H_3^+ + CH_3 \\
CH_3^+ + CH_3 & \rightarrow CH_3 = CH_2 = CH_3 + H^+
\end{align*}
\]
In a subsequent study, Devynck and co-workers\textsuperscript{81, 82} studied the electrochemical oxidation of alkanes and alkenes in triflic acid monohydrate. The acidity of CF\textsubscript{3}SO\textsubscript{3}H \cdot H\textsubscript{2}O was found to be intermediate between that of aqueous acid media and superacidity. Alkanes undergo two-electron oxidation, whereas alkenes are protonated to yield carbenium ions in this medium. In addition to various transformations characteristic of carbenium ions [Eqs. (5.36)–(5.38)], they undergo a reversible disproportionation to give an alkane and an aldehyde [Eqs. (5.40)].

\[
2 R^+ + H_2O \rightleftharpoons R'CHO + RH + 2 H^+ \quad (5.40)
\]

5.1.3. Isomerization of Alkanes

Acid-catalyzed isomerization of saturated hydrocarbons was first reported in 1933 by Nenitzescu and Dragă\c{n}.\textsuperscript{67} They found that when \textit{n}-hexane was treated with aluminum chloride under reflux, it was converted into its branched isomers. This reaction is of major economic importance as the straight-chain C\textsubscript{5}–C\textsubscript{8} alkanes are the main constituents of gasoline obtained by refining of the crude oil. Because the branched alkanes have a considerably higher octane number than their linear counterparts, the combustion properties of gasoline can be substantially improved by isomerization. Table 5.3 gives the octane number of a series of straight-chain and branched hydrocarbons.

The isomerization of \textit{n}-butane 1 to isobutane 2 is of great importance because isobutane reacts under mild acidic conditions with olefins to give highly branched hydrocarbons in the gasoline range. A substantial number of investigations have been devoted to this isomerization reaction and a number of reviews are available.\textsuperscript{83–89} The isomerization is an equilibrium reaction that can be catalyzed by various strong acids. In the industrial processes, aluminum chloride and chlorinated alumina are the most widely used catalysts. Whereas these catalysts become active only above 80–100°C, superacids are capable of isomerizing alkanes at room temperature and below. The major advantage (besides energy saving) is that lower temperatures thermodynamically favor the most branched isomers (Table 5.4).

During the isomerization process of pentanes, hexanes, and heptanes, cracking of the hydrocarbon is an undesirable side reaction. The discovery that cracking can be substantially suppressed by hydrogen gas under pressure was of significant importance. In our present-day understanding, the effect of hydrogen is to quench carboxation sites through five-coordinate carbocations to the related hydrocarbons, thus decreasing the possibility of C–C bond cleavage reactions responsible for the acid-catalyzed cracking.

The nucleophilic nature of the alkanes is also shown by the influence of the acidity level on their solubility. Torck and co-workers\textsuperscript{90} have investigated the composition of the catalytic phase obtained when \textit{n}-pentane or \textit{n}-hexane is thoroughly mixed with HF–SbF\textsubscript{5} in an autoclave under hydrogen pressure [Eq. (5.41)]. The total amount of hydrocarbon in the catalytic phase (dissolved ions and neutrals) was obtained by extraction with excess of methylcyclopentane. The amount of physically dissolved
hydrocarbons was obtained by extracting the catalytic phase with Freon 113. The amount of cations is calculated by difference. The results are shown in Figure 5.11.

\[
\text{RH} + \text{H}^+ \text{Sb}_2\text{F}_{11}^- \rightarrow \text{R}^+ \text{Sb}_2\text{F}_{11}^- + \text{H}_2 \quad (5.41)
\]

The total amount of hydrocarbons increases from 1.6% to 14.6% in weight when the SbF$_5$ concentration varies from 0 to 6.8 mol L$^{-1}$. The amount of carbenium ions increases linearly with the SbF$_5$ concentration, and the solubility of the hydrocarbon itself reaches a maximum for 5 mol L$^{-1}$ of SbF$_5$. The apparent decrease in solubility of the hydrocarbon at higher SbF$_5$ concentration may be due to the rapid rate of hydrocarbon protolysis, along with the change in the composition of the acid, causes SbF$_6^-$ anions to be transformed into Sb$_2$F$_{11}^-$ anions.

Isomerization of \textit{n}-hexane 6 in superacid proceeds by three steps: formation of the carbenium ion (step 1, Scheme 5.10), isomerization of the carbenium ion via hydride shift, alkyde shift, and protonated cyclopropane (for the branching step) (step 2,

**Figure 5.11.** Variation of the composition of the catalytic phase as a function of the SbF\(_5\) concentration in the \(n\)-pentane isomerization in HF–SbF\(_5\): \(T = 15^\circ\)C, \(p_{H_2} = 5\) bars, volume of the catalytic phase = 57 mL. \(\bullet\), Mass of C\(_5^+\); \(\circ\), mass of C\(_5\)H (Freon-113 extract); \(\triangle\), % weight of C\(_5^+\) + C\(_5\)H (methylcyclopentane extract).
Scheme 5.10, and hydride transfer from the alkane to the incipient carbenium ion (step 3, Scheme 5.10).

Whereas step 1 is stoichiometric, steps 2 and 3 form a catalytic cycle involving the continuous generation of carbenium ions via hydride transfer from a new hydrocarbon molecule (step 3) and isomerization of the corresponding carbenium ion (step 2). This catalytic cycle is controlled by two kinetic and two thermodynamic parameters that can help orient the isomer distribution, depending on the reaction conditions. Step 2 is kinetically controlled by the relative rates of hydrogen shifts, alkyl shifts, and protonated cyclopropane formation, and it is thermodynamically controlled by the relative stabilities of the secondary and tertiary ions. (This area is thoroughly studied; see Chapter 3.) Step 3, however, is kinetically controlled by the hydride transfer from excess of the starting hydrocarbon and by the relative thermodynamic stability of the various hydrocarbon isomers.

For these reasons, the outcome of reaction will be very different depending on which thermodynamic or kinetic factor will be favored. In the presence of excess hydrocarbon in equilibrium with the catalytic phase and long contact times, the thermodynamic hydrocarbon isomer distribution is attained. However, in the presence of a large excess of acid, the product will reflect the thermodynamic stability of the intermediate carbenium ions (which, of course, is different from that of hydrocarbons) if rapid hydride transfer or quenching can be achieved. Torck and co-workers\textsuperscript{90–92} have shown that the limiting step in the isomerization of \textit{n}-hexane \textit{6} and \textit{n}-pentane with the HF–SbF\textsubscript{5} acid catalyst is the hydride transfer with sufficient contact in a batch reactor, as indicated by the thermodynamic isomer distribution of C\textsubscript{6} isomers. Figure 5.12 shows the isomer distribution versus reaction time of \textit{n}-hexane \textit{6} (Hex) at 20°C.

It also shows that 2-methylpentane (\textit{16}, 2MeP), 3-methylpentane (\textit{17}, 3MeP), and 2,3-dimethylbutane (\textit{18}, 2,3DiMeBu) appear simultaneously and their concentration reaches a maximum at the same time. Their relative ratio stays the same at all times and is identical to the thermodynamically calculated one. 2,2-Dimethylbutane (\textit{19}, 2,2DiMeBu), however, appear much more slowly. The reaction network is depicted in Scheme 5.11.

The detailed kinetic study of this system shows that after the initial period during which the catalytic phase is formed, the experimental rate constant of isomerization $K_1$...
is expressed as in Eq. 5.42, in which $\beta$ is the partition coefficient of the paraffin between the hydrocarbon and the catalytic phase, $N_c$ is the number of moles in the catalytic phase, $N_0$ is the total number of moles of paraffin at the start, $[R^+]$ is the concentration of carbenium ion, and $K_{sp}$ is the temperature-dependent constant. Under external hydrogen pressure, the rate of isomerization slows down in agreement with the corresponding reduction of the carbenium ion into alkane (reverse step). This effect was found more pronounced for weaker superacids ($\text{SbF}_5$ content $< 2 \text{ mol L}^{-1}$).

$$K_1 = K_{sp} [R^+] \beta \frac{N_c}{N_0}$$

(5.42)
The isomerization of \( n \)-pentane in superacids of the type \( R_F\text{SO}_3\text{H–SbF}_5 \) (\( R_F = \text{C}_n\text{F}_{2n+1} \)) has been investigated by Commeyras and co-workers.\(^9\) The influence of parameters such as acidity (A), hydrocarbon concentration (B), nature of the perfluoroalkyl group (C), total pressure (D), hydrogen pressure (E), temperature (F), and agitation has been studied. Only A, C, E, and F have been found to have an influence on the isomerization reaction in accordance with such reactions in the \( \text{HF–SbF}_5 \) system.

In weaker superacids such as neat \( \text{CF}_3\text{SO}_3\text{H} \), alkanes that have no tertiary hydrogen are isomerized only very slowly, because the acid is not strong enough to hydride abstract to form the initial carbocation. This lack of reactivity can be overcome by introducing initiator carbenium ions in the medium to start the catalytic process. For this purpose, alkenes may be added, which are directly converted into their corresponding carbenium ions by protonation, or alternatively the alkane may be electrochemically oxidized (anodic oxidation) \([\text{Eq. (5.43)}]\). Both methods are useful to initiate isomerization and cracking reactions. The latter method has been studied by Commeyras and co-workers,\(^9\text{a},9\text{b}\) who came to the conclusion that it was much more favorable for side reactions such as condensation and cracking of alkanes than for simple isomerization reactions. Considering the low superacidity of the medium used, the result is in good agreement with the predictions of the acidity–potential diagrams described earlier.

\[
\begin{align*}
\text{RH} & \quad \text{RH}^+ \quad \text{R}^+ \\
& \quad \text{R}^+ \\
\text{RH} & \quad \text{R}^+ \\
\rightarrow & \quad \text{R}^+
\end{align*}
\]

\(5.43\)

Olah\(^9\text{c}\) has developed a method wherein natural gas liquids containing saturated straight-chain hydrocarbons can be conveniently upgraded to highly branched hydrocarbons (gasoline upgrading) using triflic acid, HF and a Lewis acid (\( \text{BF}_3, \text{PF}_5, \text{AsF}_5, \text{SbF}_5, \text{TaF}_5, \text{NbF}_5 \)). The addition of small amount of olefins, preferably butenes, helped the reaction rate. This can be readily explained by the formation of alkyl fluorides (HF addition to olefins), whereby an equilibrium concentration of cations is maintained in the system during the upgrading reaction. The gasoline upgrading process is also improved in the presence of hydrogen gas, which helps to suppress side reactions such as cracking and disproportionation and minimize the amount of hydrocarbon products entering the catalyst phase of the reaction mixture. The advantage of the above method is that the catalyst \( \text{HF–BF}_3 \) (being gases at ambient temperatures) can easily be recovered and recycled. Olah has also found \( \text{HSO}_3\text{F} \) and related superacids are efficient catalysts for the isomerization of \( n \)-butane to isobutane.\(^9\text{d}\) Isomerization carried out in a flow system with fluorosulfuric acid containing up to 5% HF as a co-acid at 21°C gave \( \sim 70\% \) conversion to isobutane with generally less than 3% cracking.\(^9\text{e}\) The acidity of the \( \text{HF–HSO}_3\text{F} \) system decreases significantly with higher amounts of HF; consequently, isomerization becomes less efficient. Under superacid conditions, butane isomerization is an intramolecular reaction proceeding through protonated methylcyclopropanes \([\text{Eq. (5.44)}]\). This process, however, differs from that of higher alkanes in that the secondary 2-butyl cation \( (3) \) cannot undergo facile \( \beta \)-scission.
This is why cracking is not significant in butane isomerization. In contrast, prolonged reaction of pentane and hexane in this acid system resulted in predominant protolytic cleavage.

\[
\begin{align*}
\text{3} & \rightarrow \left[ \text{H} \right]^+ \rightarrow \text{4} \\
\text{+} & + \text{CH}_3^+
\end{align*}
\]

(5.44)

Fărcașiu and Lukinskas have studied the isomerization of C₆ hydrocarbons (hexane, 3-methylpentane) in triflic acid (a two-phase system) under mild conditions (below 42 °C). It was observed that the immediate vicinity of the liquid–liquid interphase became yellow. If left undisturbed, dehydrogenation (formation of alkenyl cations) took place and then, after an induction period, rapid transformation was observed, resulting in the formation of mostly cracking and disproportionation products. The induction period could be reduced by the addition of one-electron oxidizers such as Fe^{3+} ions. When the reaction mixture was shaken periodically or a mild magnetic stirring was applied, isomerization became the main reaction with a much lower overall rate. Significant cracking was also observed in the homogenized reaction but only after a much longer period, when the concentration of the alkenyl cations reached a critical concentration throughout the acid phase. This was interpreted as the isomerization mode being an induction period to the cracking mode with features of a free-radical chain reaction.

Cracking and disproportionation in the reaction of hexane could be suppressed by the addition of cycloalkanes (cyclohexane, methylcyclopentane, cyclopentane). Furthermore, 3-methylpentane and methylcyclopentane also reduced the induction period. These data indicate that reactions are initiated by an oxidative formation of alkene intermediates. These may be transformed into alkenyl cations, which undergo cracking and disproportionation. When there is intensive contact between the phases ensuring effective hydride transfer, protonated alkenes give isomerization products.

The relative reactivity of hexane and 3-methylpentane (about 1000) in the isomerization mode was shown to be the same as found for isomerization in HF–SbF₅. In the cracking mode, however, the ratio is about 10, resulting from the dramatic acceleration of the reaction of hexane compared to that of 3-methylpentane. Further characteristics of the cracking mode are a large excess of branched isomers in the C₄–C₅ fractions, the absence of unsaturated cracking products, and formation of dibranched C₆ products, particularly 2,2-dimethylbutane. These features are very similar to those found in zeolite catalysis.

The difficulties encountered in handling liquid superacids and the need for product separation from the catalyst in batch processes have stimulated research in
the isomerization of alkanes over solid superacids. The isomerization of 2-methylpentane (16), 3-methylpentane (17), and 2,3-dimethylbutane (18), using SbF₅-intercalated graphite as a catalyst, has been studied in a continuous flow system.¹⁰⁴,¹⁰⁵ The isomerization reaction carried out at −30°C, −17°C, and room temperature shows an unusually high activity of this catalyst. At −17°C, conversions over 50% with a selectivity over 99% in nonbranching isomerization could be achieved. For comparison, to obtain the same conversion with acidic zeolites, temperatures as high as 180°C are necessary. At room temperature, the activity of the catalyst is higher, but branching and cracking reactions compete. The study of the skeletal rearrangement of ¹³C-labeled 2-methylpentane, 3-methylpentane, and 2,3-dimethylbutane has been carried out over the same catalyst under similar conditions.¹⁰⁶ Despite the high conversion, very little scrambling occurs. The isomerization process involves only intramolecular rearrangement of the hexyl ions and can be fully described in terms of 1,2-hydride, methide, or ethide shifts and protonated cyclopropane intermediates. The advantage of the ¹³C tracer technique is to differentiate between mono- and multimolecular processes and to remove the degeneracy of otherwise indistinguishable pathways. Combined with a flow system, it allows the investigation of the initial steps under kinetic control. For example, in the isomerization process of 2-methylpentane to 3-methylpentane, it permits distinguishing between the methyl and ethyl shift and estimating the relative rates of these two alkyde shifts.

When 3-methyl[³¹³C]pentane (17') is isomerized to 2-methylpentane, the label distribution shows that the isomerization cannot be explained by a simple 1,2-methide shift: 30% of the 2-methylpentane has the ¹³C label in a position that can be best explained by the ethyl shift (Scheme 5.12). The recovered 3-methylpentane (96%) also shows a very large degree of internal shift [Eq. (5.45)].

\[
\begin{align*}
17' & \quad \text{96% recovered} \\
\quad & \quad \text{89%} \quad \text{11%} \\
\end{align*}
\]

(5.45)

The rate of ethyl shift in this reaction is three times as high as the apparent rate of conversion of 3-methylpentane to 2-methylpentane. A simple calculation shows that
the ethyl shift is about four times faster than the methyl shift in this isomerization process. The occurrence of a competitive ethyl shift in the 3-methyl-3-pentenyl ion has been studied by Olah and co-workers under stable ion condition. Subsequently, Sommer and co-workers\textsuperscript{107} showed by using the deuterium-labeled 3-methyl-3-pentenyl ion that the ratio of ethyl:methyl shift was the same both in Magic Acid and in the presence of solid superacid. SbF\(_5\)-intercalated graphite has also been shown to exhibit a 99\% selectivity in n-pentane skeletal isomerization at room temperature in a batch process\textsuperscript{108} (48\% conversion after 2 h). The selectivity in isomerization of n-hexane was much lower because of the competing cracking process described earlier. However, in the presence of HF, the selectivity of the catalyst substantially improves as shown by the skeletal isomerization of n-hexane (96\% selectivity with 86\% conversion after 2 h). The major drawback in the extended use of this catalyst system is its relatively rapid deactivation (studied by Heinerman and Gaaf\textsuperscript{109}).

The isomerization of cycloalkanes over SbF\(_5\)-intercalated graphite can be achieved at room temperature without the usual ring opening and cracking reactions, which occur at higher temperatures and lower acidities.\textsuperscript{110} In the presence of excess hydrocarbon after several hours, the thermodynamic equilibrium is reached for the isomers. Interconversion between cyclohexane (20) and methylcyclopentane (21) yields the thermodynamic equilibrium mixture [Eq. (5.46)].

The thermodynamic ratio for the neutral hydrocarbon isomerization is very different as compared with the isomerization of the corresponding ions. The large energy difference (> 10 kcal mol\(^{-1}\)) between secondary cyclohexyl cation 22 and the tertiary methylcyclopentyl ion 23 means that in the presence of excess superacid, only the latter can be observed [Eq. (5.47)].

When a mixture of cis- and trans-decalins 24 (61.5:38.5) are treated with the same solid superacid at 0°C, the thermodynamic equilibrium is rapidly achieved\textsuperscript{110} [Eq. (5.48)]. In the reaction, decalin 24 serves as the solvent, substrate, and the hydride donor. When the equilibrium is reached, the hydrocarbon can be separated from the catalyst by simple filtration. Perhydroindane 25 was also isomerized under
mild condition at 0°C to the thermodynamic equilibrium mixture\textsuperscript{110} [Eq. (5.48)].

(5.48)

The potential of other solid superacid catalysts, such as Lewis-acid-treated metal oxides for skeletal isomerization of hydrocarbons, has been studied in a number of cases. The reaction of \( n \)-butane \( 1 \) with \( \text{SbF}_5\)–\( \text{SiO}_2\)–\( \text{TiO}_2 \) gave the highest conversion forming \( \text{C}_3 \), iso\( \text{C}_4 \), iso\( \text{C}_5 \), and traces of higher alkanes (Table 5.5). \( \text{TiO}_2\)–\( \text{SbF}_5 \), on the other hand, gave the highest selectivity for skeletal isomerization of \( n \)-butane. With \( \text{SbF}_5\)–\( \text{Al}_2\text{O}_3 \), however, the conversions were very low (Table 5.5).\textsuperscript{111,112}

Similarly, isomerization of pentane and 2-methylbutane over a number of \( \text{SbF}_5\)-treated metal oxides has been investigated.\textsuperscript{113} \( \text{SbF}_5\)–\( \text{TiO}_2\)–\( \text{ZrO}_2 \) system was the most reactive and at the maximum conversion the selectivity for skeletal isomerization was found to be about 100\%. Table 5.6 summarizes the effect of temperature on desorption of \( \text{SbF}_5 \) out of the catalyst and shows that with increasing temperature, the weight \% of the retained Lewis acid decreases.

A comparison of the reactivity of \( \text{SbF}_5\)-treated metal oxides with that of \( \text{HSO}_3\)F-treated catalysts showed that the former is by far the better catalyst for the reaction of alkanes at room temperature, although the \( \text{HSO}_3\)F-treated catalyst showed some potential for isomerization of \( 1 \)-butene.\textsuperscript{111}

\( \text{SbF}_5\)–\( \text{SiO}_2\)–\( \text{Al}_2\text{O}_3 \) has been used to isomerize a series of alkanes at or below room temperature. Methylcyclopentane, cyclohexane, propane, butane, 2-methylpropane, and pentane all reacted at room temperature, whereas methane, ethane, and 2,2-dimethylpropane could not be activated.\textsuperscript{111}

An IR study of \( \text{SbF}_5\)–\( \text{Al}_2\text{O}_3 \) after addition of pyridine to the catalyst shows an absorption at 1460 cm\textsuperscript{-1}, which is assigned to pyridine coordinated with the Lewis acid site, and shows another absorption at 1540 cm\textsuperscript{-1}, which is attributed to the pyridinium ion resulting from the protonation of pyridine by the Brønsted acid sites. When the catalyst is heated up to 300°C, the IR band of the pyridinium ion disappears, whereas the absorption for the Lewis acid is still present. The fact that the catalyst is still active for \( n \)-butane isomerization suggests that the Lewis acid sites are the active sites for the catalysis.\textsuperscript{111}

Methane produced in the reaction of butane with \( \text{SbF}_5\)–\( \text{SiO}_2\)–\( \text{Al}_2\text{O}_3 \) did not contain any deuterium when the surface OH groups of the catalyst were replaced by OD. Furthermore, no hydrogen evolution could be detected in these reactions.

\(^a\) Reacted at 200°C.

\(^b\) 2,3-Dimethylbutane, 2-methylpentane, 3-methylpentane.
Two alternative mechanisms have been suggested. (i) The reactions are initiated by hydride abstraction from the alkane by the Lewis acid to form a carbenium ion, and not by protonation of the C–C bond of \( n \)-butane. (ii) \( n \)-Butane is protonated by the Brønsted acid to form a carbonium ion intermediate; and either the hydrogen formed is used up to reduce SbF\(_5\) or it loosely remains bound to the ion during the isomerization process.\footnote{111}

The isomerization of a large number of C\(_{10}\) hydrocarbons under strongly acidic conditions gives the unusually stable isomer adamantane.\footnote{26} The first such isomerization was reported by Schleyer in 1957.\footnote{114} During a study of the facile aluminum chloride-catalyzed endo–exo isomerization of tetrahydrodicyclopentadiene (trimethylenenorbornane)\footnote{27}, difficulty was often encountered with a highly crystalline material that often clogged distillation heads. This crystalline material was found to be adamantane.\footnote{26} Adamantane can be prepared from a variety of C\(_{10}\) precursors and involves a series of hydride and alkyde shifts. Scheme 5.13 shows the rearrangement map of C\(_{10}\) hydrocarbons to adamantane. The mechanism of the reaction has been reviewed in detail.\footnote{115} Fluoroantimonic acid (HF–SbF\(_5\)) very effectively isomerizes tetrahydrodicyclopentadiene into adamantane\footnote{27} in high yields\footnote{\( \text{Eq. (5.49)} \)}. Sonication was shown to accelerate isomerization. Furthermore, the same catalysts could be

successively applied to transform $\text{C}_{14}\text{H}_{20}$ and $\text{C}_{18}\text{H}_{24}$ precursors to diamantane [Eq. (5.50)] and triamantane, respectively.\textsuperscript{118}
The superelectrophilic $\text{AcBr}_n\text{AlBr}_3$ complexes, called aprotic organic superacids developed by Vol’pin and co-workers,$^{119,120}$ were used in the isomerization of $\text{C}_{12}\text{H}_{20}$ tricyclanes with the main component being perhydroacenaphthene to dimethyl- and ethyladamantanes$^{121}$ [Eq. (5.51)].

Another example of superacid-catalyzed formation of an unusually stable highly symmetric hydrocarbon has been provided by Paquette and Balogh$^{122}$ in the synthesis of 1,16-dimethylidodecahedrane 28 [Eq. (5.52)].

Two mechanistic schemes (Schemes 5.14 and 5.15) via carbocationic intermediates have been proposed by Paquette and Balogh.$^{122}$ The reaction path depicted in Scheme 5.14 involves Wagner–Meerwein shifts of the methyl group prior to cyclization followed by hydride shift to a number of cationic intermediates. The second scheme (Scheme 5.15) depicts ring closure before methyl migration. The first step involves protolysis of the C–H bond next to the methyl-bearing carbon. The corresponding ion can then rearrange by a 1,2-methyl shift and yield 1,16-dimethylidodecahedrane 28 by hydride abstraction from a hydride donor.
An unusual isomerization of perhydro[2.2]paracyclophane 29, an *out–in* hydrogen transfer process, was observed in triflic acid\(^{123}\) [Eq. (5.53)]. Reaction in CF\(_3\)SO\(_3\)D resulted in the incorporation of up to five deuteriums without specific locations. The authors suggested the backside attack of the inside hydrogen (H\(_i\)) to the bridgehead
carbon participating in 2e–3c bonding (29) as the key step in the isomerization.

5.1.4. Cleavage Reactions (β-Cleavage versus C–C Bond Protolysis)

The reduction in molecular weight of various fractions of crude oil is an important operation in petroleum chemistry. The process is called cracking. Catalytic cracking is usually achieved by passing the hydrocarbons over a metallic or acidic catalyst, such as zeolites at about 400–600°C. The molecular weight reduction involves carbocationic intermediates and the mechanism is based on the β-scission of carbenium ions [Eq. (5.54)]. The main goal of catalytic cracking is to upgrade higher boiling oils, which, through this process, yield lower hydrocarbons in the gasoline range.\textsuperscript{124–126}

Historically, the first cracking catalyst used was aluminum trichloride. With the development of heterogeneous solids and supported catalysts, the use of AlCl\textsubscript{3} was soon superseded, since its activity was mainly due to the ability to bring about acid-catalyzed cleavage reactions.

The development of highly acidic superacid catalyst in the 1960s again focused attention on acid-catalyzed cracking reactions. HSO\textsubscript{3}F–SbF\textsubscript{5}, trade-named Magic Acid, derived its name (see Section 2.2.2.2) from its remarkable ability to cleave higher-molecular-weight hydrocarbons, such as paraffin wax, to lower-molecular-weight components, preferentially C\textsubscript{4} and other branched isomers.

As a model for cracking of alkanes, the reaction of 2-methylpentane (16, 2MeP) over SbF\textsubscript{5}-intercalated graphite has been studied in a flow system, with the hydrocarbon being diluted in a hydrogen stream.\textsuperscript{104,105} A careful study of the product
distribution versus time on stream showed that propane was the initial cracking product whereas isobutane and isopentane (as major cracking products) appeared only later (Figure 5.13).

This result can only be explained by the \( \beta \)-scission of the trivalent 4-methylpent-2-yl ion \( 30 \) as the initial step in the cracking process. Based on this and on the product distribution versus time profile, a general scheme for the isomerization and cracking process of the methylpentanes has been proposed\(^ {103,104} \) (Scheme 5.16).

Propene (32), which is formed in the \( \beta \)-scission step, never appears as a reaction product because it is alkylated immediately under the superacid condition by a \( \text{C}_6^+ \) carbenium ion (MeP\(^+ \)), forming a \( \text{C}_9^+ \) carbocation, which is easily cracked to form an iso \( \text{C}_4^+ \) or iso \( \text{C}_5^+ \) ion and the corresponding \( \text{C}_4 \) or \( \text{C}_5 \) alkene (\( \text{C}_4^- \), \( \text{C}_5^- \)). The alkenes are further alkylated by a \( \text{C}_6^+ \) carbenium ion in a cyclic process of alkylation and cracking reactions. The \( \text{C}_4^+ \) or \( \text{C}_5^+ \) ions also give the corresponding alkanes [isobutane, iso\( \text{C}_4 \)H and isopentane, iso\( \text{C}_5 \)H] by hydride transfer from the starting methylpentane. This scheme, which occurs under superacidic conditions, is at a variance with the scheme that was proposed for the cracking of \( \text{C}_6 \) alkanes under less acidic conditions (Scheme 5.17).\(^ {94,95} \)

Under superacidic conditions, it is known that the deprotonation equilibria (Scheme 5.17, first reaction) lie too far to the left (\( K = 10^{-16} \) for isobutane\(^ {127} \)) to make this pathway plausible. On the other hand, among \( \text{C}_6 \) isomers, 2MeP is by far the easiest to cleave by \( \beta \)-scission. The 4-methylpent-2-yl ion \( 30 \) is the only species that does not give a primary cation by this process. For this reason, this ion is the key intermediate in the isomerization cracking reaction of \( \text{C}_6 \) alkanes.

Figure 5.13. Distribution of cracking products (mass\%) of 2-methylpentane (16) versus time on stream at 20°C.\(^ {104} \)
Scheme 5.16

Scheme 5.17
Under superacid conditions, $\beta$-scission is not the only pathway by which hydrocarbons are cleaved. The C–C bond can also be cleaved by protolysis [Eq. (5.55)].

$$\text{C–C} + H^+ \rightarrow \begin{array}{c} \text{H} \\ \text{C–C–C} \end{array}^+ \rightarrow \text{C}^+ + \text{CH}$$  \hspace{1cm} (5.55)

The protolysis under superacid conditions has been studied independently by Olah$^{128}$ and Hogeveen and co-workers$^{19,20,129}$ The carbon–carbon cleavage in neopentane (7) yielding methane and the tert-butyl cation 4 occurs by a mechanism different from the $\beta$-scission of carbenium ions [Eq. (5.56)].

$$\begin{array}{c} \text{CH}_3 \\ \text{CH}_3 \\ \text{CH}_3 \\ \text{CH}_3 \\ \text{H} \end{array} \rightarrow \begin{array}{c} \text{H} \\ \text{CH}_3 \\ \text{CH}_3 \\ \text{CH}_3 \\ \text{CH}_3 \end{array}^+ \rightarrow (\text{CH}_3)_{3}C^+ + \text{CH}_4$$  \hspace{1cm} (5.56)

The protolysis occurs following the direct protonation of the $\sigma$-bond providing evidence for the $\sigma$-basicity of hydrocarbons. Under slightly different conditions, protolysis of a C–H bond occurs, yielding rearranged tert-amyl cation 33 (2-methylbut-2-yl cation) [Eq. (5.57)]. In cycloalkanes, the C–C bond cleavage leads to ring opening [Eq. (5.58)].

$$\begin{array}{c} (\text{CH}_3)_{3}C–\text{CH}_3 \end{array} + H^+ \rightarrow \begin{array}{c} \text{H} \\ (\text{CH}_3)_{3}C–\text{CH}_2 \end{array}^+ \rightarrow \begin{array}{c} \text{CH}_3 \\ \text{CH}_3 \end{array} + \text{CH}_2\text{CH}_3$$  \hspace{1cm} (5.57)

$$\begin{array}{c} \text{C} \end{array} + H^+ \rightarrow \begin{array}{c} \text{H} \end{array}^+ \rightarrow \text{H}$$  \hspace{1cm} (5.58)

This reaction is much faster than the carbon–carbon cleavage in neopentane, despite the initial formation of secondary carbenium ions. Norbornane is also cleaved in a fast reaction, yielding substituted cyclopentyl ions. Thus, protonation of alkanes induces cleavage of the molecule by two competitive ways: (i) protolysis of a C–H bond followed by $\beta$-scission of the carbenium ions and (ii) direct protolysis of a C–C bond yielding a lower-molecular-weight alkane and a lower-molecular-weight carbenium ion.
This reaction, which is of economic importance in the upgrading of higher boiling petroleum fractions to gasoline, has also been shown applicable to coal depolymerization and hydroliquefaction processes.\textsuperscript{130–132} The cleavage of selected model compounds representing coal structural units in the presence of HF and BF\textsubscript{3} and under hydrogen pressure has been studied by Olah et al.\textsuperscript{130} Bituminous coal (Illinois No. 6) could be pyridine-solubilized to the extent of 90\% by treating it with HF–BF\textsubscript{3} catalyst in the presence of hydrogen gas at 105°C for 4 h. Under somewhat more elevated temperatures (150–170°C), cyclohexane extractability of up to 22\% and distillability of up to 28\% was achieved. Addition of hydrogen donor solvents such as isopentane has been shown to improve the efficiency of coal conversion to cyclohexane-soluble products. The initial depolymerization of coal involves various protolytic cleavage reactions involving those of C–C bonds. HF–BF\textsubscript{3} was also shown to be a highly effective catalyst for the hydrocracking of oil sand bitumens evidenced by a high conversion of the bitumen to volatiles (56\%).\textsuperscript{133} When methycyclohexane is applied as a hydrogen-donor solvent, new products are formed resulting from the oligomerization of methycyclohexane. This points to possible complications arising in the application of hydrocarbons as stabilizers or hydrogen donors, since oligomerization consumes the hydrocarbons and the highly reactive polyenic oligomers formed may induce secondary reactions during product analyses.

Shimizu et al. have reported the use of triflic acid, HF, and BF\textsubscript{3} in the liquefaction of coals of various origins. Triflic acid was effective to convert lignite and Taiheiyo coal to pyridine-solubles almost completely in the presence of isopentane without hydrogen (150°C, 3 h).\textsuperscript{134–136} Relatively low conversions with diphenyl ether and biphenyl as model compounds indicated that aromatic ether and aryl–aryl linkages are more difficult to cleave under these conditions. Solubilization was mainly attributed to cleavage of methylene bridges in the coal. Desulfurization of lignite (35.4–41.3\%) was achieved with triflic acid in toluene originating mainly from sulfides.\textsuperscript{137} Mixtures of HF and BF\textsubscript{3} were found to be highly effective in the depolymerization of Miike bituminous coal and Taiheiyo subbituminous coal in toluene.\textsuperscript{138,139} The high effectiveness of the HF–BF\textsubscript{3} system was ascribed to its ability to efficiently cleave both ether groups and methylene bridges. Since both deoxygenation and depolymerization are required for Yallourn lignite, it underwent solubilization under more forcing conditions (higher acidity, elevated temperature).

A combination of triflic acid with iodine was shown to be effective to liquefy three types of coal in toluene or tetralin under hydrogen pressure.\textsuperscript{141} The major role of acid was found to enhance coal depolymerization to asphaltenes, whereas the main function of iodine was to hydrogenate and hydrocrack asphaltenes to oils. The combined catalytic system removed 50\% of the nitrogen and 90\% of the sulfur of the coals (Illinois No. 6 and Pittsburg seam samples).

5.1.5. Alkylation of Alkanes and Oligocondensation of Lower Alkanes

The alkylation of alkanes by olefins, from a mechanistic point of view, must be considered as the alkylation by the carbenium ion formed by the protonation of the olefin. The well-known acid-catalyzed isobutane–isobutylene reaction demonstrates the mechanism rather well (Scheme 5.18).
As is apparent in the last step, isobutane is not alkylated but transfers a hydride to the $\text{C}_8^+\text{H}_8$ carbocation before being used up in the middle step as the electrophilic reagent (tert-butyl cation 4). The direct alkylation of isobutane by an incipient tert-butyl cation would yield 2,2,3,3-tetramethylbutane,\textsuperscript{142} which indeed was observed in small amounts in the reaction of tert-butyl cation with isobutane under stable ion conditions at low temperatures (\textit{vide infra}).

The alkylating ability of methyl and ethyl fluoride–antimony pentafluoride complexes has been investigated by Olah et al.,\textsuperscript{143,144} who showed the extraordinary reactivity of these systems. Self-condensation was observed as well as alkane alkylation. When $\text{CH}_3\text{F–SbF}_5$ was reacted with excess of $\text{CH}_3\text{F}$ at $0^\circ\text{C}$, at first only an exchanging complex was observed in the $^1\text{H}$ NMR spectrum. After 0.5 h, the starting material was converted into the tert-butyl cation 4 (Scheme 5.19).

![Scheme 5.18](image)

Scheme 5.18

Similar reactions were observed with the $\text{CH}_3\text{CH}_2\text{F–SbF}_5$ complex (Scheme 5.19). When the complex was treated with isobutane or isopentane, direct alkylation products were observed [Eq. (5.59)].

![Scheme 5.19](image)

Scheme 5.19

$$
\text{FCH}_3 + \text{CH}_3\text{F} \rightarrow \text{SbF}_5 \\
\text{FCH}_2\text{CH}_3 + \text{CH}_3\text{CH}_2\text{F} \rightarrow \text{SbF}_5 \rightarrow \text{FCH}_2\text{CH}_2\text{CH}_3 \rightarrow (\text{CH}_3)_3\text{C}^+ \tag{5.59}
$$
To improve the understanding of these alkane alkylation reactions, Olah and his group carried out experiments involving the alkylation of lower alkanes by stable carbenium ions under controlled superacidic stable ion conditions \[128,145,146\] [Eq. (5.60)].

\[
\text{R-H} + \text{R}^+ \rightarrow \left[ \begin{array}{c} \text{H} \\ \text{R}^+ \end{array} \right] \rightarrow \text{R-R'} + \text{H}^+ \quad (5.60)
\]

The $\sigma$-donor ability of the C–C and C–H bonds in alkanes was demonstrated from a variety of examples. The order of reactivity of single bonds was found to be tertiary C–H $>$ C–C $>$ secondary C–H $>$ primary C–H, although various specific factors such as steric hindrance can influence the relative reactivities.

Typical alkylation reactions are those of propane, isobutane, and $n$-butane by the tert-butyl or sec-butyl ion. These systems are somewhat interconvertible by competing hydride transfer and rearrangement of the carbenium ions. The reactions were carried out using alkyl carbenium ion hexafluoroantimonate salts prepared from the corresponding halides and antimony pentafluoride in sulfuryl chloride fluoride solution and treating them in the same solvent with alkanes. The reagents were mixed at $-78^\circ$C warmed up to $-20^\circ$C and quenched with ice water before analysis. The intermolecular hydride transfer between tertiary and secondary carbenium ions and alkanes is generally much faster than the alkylation reaction. Consequently, the alkylation products are also those derived from the new alkanes and carbenium ions formed in the hydride transfer reaction.

Propylation of propane by the isopropyl cation 31, for example, gives a significant amount (26% of the C$_6$ fraction) of the primary alkylation product [Eq. (5.61)].

\[
\text{31} \quad + \quad \text{H-} \rightarrow \left[ \begin{array}{c} \text{H} \\ \text{31} \end{array} \right] \rightarrow \text{31} \quad -\text{H}^+ \quad (5.61)
\]

The C$_6$ isomer distribution—2-methylpentane (28%), 3-methylpentane (14%), and $n$-hexane (32%)—is very far from thermodynamic equilibrium, and the presence of these isomers indicates that both isopropyl cation 31 [Eq. (5.62)] and $n$-propyl cation 34 [Eq. (5.63)] are involved as intermediates [as shown by $^{13}$C(2)–$^{13}$C(1) scrambling in the stable ion $^{147}$].

\[
\text{31} \quad + \quad \text{H} \rightarrow \text{C}_6 \quad -\text{H}^+ \quad (5.62)
\]

\[
\text{34} \quad + \quad \text{H} \rightarrow \text{C}_6 \quad -\text{H}^+ \quad (5.63)
\]
The strong competition between alkylation and hydride transfer appears in the alkylation reaction of propane by butyl cations, or butanes by the propyl cation. The amount of C\textsubscript{7} alkylation products is rather low. This point is particularly emphasized in the reaction of propane by the tert-butyl cation, which yields only 10\% of heptanes. In the interaction of isopropyl cation \textbf{31} with isobutane \textbf{2} the main reaction is hydride transfer from the isobutane to the isopropyl ion followed by alkylation of propane by the isopropyl ions (Scheme 5.20).

Even the alkylation of isobutane by the tert-butyl cation \textbf{4} despite the highly unfavorable steric interaction has been demonstrated\textsuperscript{142} by the formation of small amounts of 2,2,3,3-tetramethylbutane \textbf{36}. This result also indicates that the related five-coordinate carbocationic transition state (or high-lying intermediate) \textbf{35} of the degenerate isobutylene–tert-butyl cation hydride transfer reaction is not entirely linear, despite the highly crowded nature of the system (Scheme 5.21).

2,2,3,3-Tetramethylbutane \textbf{36} was not formed when \textit{n}-butane and \textit{sec}-butyl cation were reacted. The isomer distribution of the octane isomers for typical butyl cation–butane alkylations is shown in Table 5.7.

Alkylation of methane, ethane, propane, and \textit{n}-butane by the ethyl cation generated via protonation of ethylene in superacid media has been studied by Siskin,\textsuperscript{148} Sommer et al.,\textsuperscript{149} and Olah et al.\textsuperscript{150} The difficulty lies in generating in a controlled way a very energetic primary carbenium ion in the presence of excess methane and at the same time avoiding oligocondensation of ethylene itself. Siskin carried out the reaction of
methane–ethylene (86:14) gas mixture through a 10:1 HF–TaF$_5$ solution under pressure with strong mixing. Among the recovered reaction products 60% of C$_3$ was found (propane and propylene) [Eq. (5.64)]. Propylene is formed when propane, which is substantially a better hydride donor, reacts with ethyl cation [Eq. (5.65)].

\text{CH}_3\text{CH}_2\text{CH}_3 & + [\text{CH}_3^+\text{CH}_2] \quad \xrightarrow{\text{[CH}_3^+\text{CH}_2}_2^-} \text{CH}_3\text{CH}_3 + \text{CH}_3^+\text{CH}^-\text{CH}_3 \quad \xrightarrow{\text{[CH}_3^+\text{CH}_2}_2^-} \text{CH}_3\text{CH}^-\text{CH}=\text{CH}_2 \\
\end{align*}
\]

(5.64)

(5.65)

Propane as a degradation product of polyethylene (a byproduct in the reaction) was ruled out because ethylene alone under the same conditions does not give any propane. Under similar conditions but under hydrogen pressure, polyethylene reacts quantitatively to form C$_3$ to C$_6$ alkanes, 85% of which are isobutane and isopentane. These results further substantiate the direct alkane alkylation reaction and the intermediacy of the pentacoordinate carbonium ion. Siskin also found that when ethylene was allowed to react with ethane in a flow system, n-butane was obtained as the sole product, indicating that the ethyl cation is alkylating the primary C–H bond through a five-coordinate carbonium ion [Eq. (5.66)].
If the ethyl cation would have reacted with excess ethylene, primary 1-butyl cation would have been formed, which irreversibly would have rearranged to the more stable sec-butyl and subsequently tert-butyl cations giving isobutane as the end product.

Superacid-catalyzed alkylation of adamantane with lower alkenes (ethene, propene, isomeric butenes) has been investigated by Olah et al.\textsuperscript{151} in triflic acid and triflic acid–B(OSO\textsubscript{2}CF\textsubscript{3})\textsubscript{3}. Only trace amounts of 1-tert-butyladamantane (37) were detected in alkylation with 1- and 2-butenes, whereas isobutylene gave consistently relatively good yield of 37. Since isomerization of isomeric 1-butyladamantane under identical conditions did not give even traces of 37, its formation can be accounted for by \(\sigma\)-alkylation, that is, through the insertion of the tert-butyl cation into the C–H bond (Scheme 5.22). This reaction is similar to that between tert-butyl cation and isobutane to form 2,2,3,3-tetramethylbutane discussed above (Scheme 5.21). In either case, the pentacoordinate carbocation intermediate, which may also lead to hydride transfer, does not attain a linear geometry, despite the unfavorable steric interactions.

The yield of the alkane–alkene alkylation in homogeneous HF–TaF\textsubscript{5} depending on the alkene–alkane ratio has been investigated by Sommer et al.\textsuperscript{149} in a batch system with short reaction times. The results support direct alkylation of methane, ethane, and propane by the ethyl cation and the product distribution depends on the alkene–alkane ratio (Figure 5.14).

Despite the unfavorable experimental conditions in a batch system for kinetically controlled reactions, a selectivity of 80\% in \(n\)-butane was achieved through ethylation of ethane. The results show, however, that to succeed in the direct alkylation the following conditions have to be met. (i) The olefin should be completely converted to

\begin{equation}
\text{H}_2\text{C} = \text{CH}_2 \rightarrow \text{CH}_3\text{CH}_2^+ \text{CH}_3\text{CH}_3 \rightarrow \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_3^+ \rightarrow \text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_3
\end{equation}

(Scheme 5.22)
the reactive cation (incomplete protonation favors the polymerization and cracking processes); this means the use of a large excess of acid and good mixing. (ii) The alkylation product must be removed from the reaction mixture before it transfers a hydride to the reactive cation, in which case the reduction of the alkene is achieved. (iii) The substrate to cation hydride transfer should not be easy; for this reason the reaction shows the best yield and selectivity when methane and ethane are used.

The direct ethylation of methane with ethylene was also investigated by Olah et al. using $^{13}$C-labeled methane (99.9 $^{13}$C) over solid superacid catalysts such as TaF$_5$–AlF$_3$, TaF$_5$, and SbF$_5$–graphite. Product analyses by gas chromatography–mass spectrometry (GC–MS) are given in Table 5.8.

(5.67)

An increase in the alkene–alkane ratio results in a significant decrease in single-labeled propane; ethylene polymerization–cracking and hydride transfer become the main reaction. This labeling experiment carried out under conditions where side reactions were negligible is indeed unequivocal proof for the direct alkylation of an alkane by a very reactive carbenium ion.

Corma and co-workers$^{152}$ have performed a detailed theoretical study (B3PW91/6-31G* level) of the mechanism of the reactions between carbenium ions and alkanes (ethyl cation with ethane and propane and isopropyl cation with ethane, propane, and isopentane) including complete geometry optimization and characterization of the reactants, products, reaction intermediates, and transition states involved. Reaction enthalpies and activation energies for the various elemental steps and the equilibrium constants and reaction rate constants were also calculated. It was concluded that the interaction of a carbenium ion and an alkane always results in the formation of a carbonium cation, which is the intermediate not only in alkylation but also in other hydrocarbon transformations (hydride transfer, disproportionation, dehydrogenation).

Olah et al.$^{153}$ have made detailed studies of the use of triflic acid in the isobutane–isobutylene alkylation. A high-quality alkylate with about 70% branched C$_8$ isomers could be produced at $-30^\circ$C with a catalyst/hydrocarbon ratio of 0.5. At higher temperatures and longer residence time, cracking becomes significant, resulting in the formation of increasing amounts of products of low molecular weight (light end) (Scheme 5.23). Triflic acid could be recycled several times without purification to produce alkylates of good quality and contained low amounts of acid-soluble oils (ASO) after four cycles. Acid-soluble oils are conjunct polymers and formed primarily from the decomposition of ester intermediates.$^{154,155}$ These are rich in heavy

![Scheme 5.23](image-url)
isoalkanes and alkenes and dilute the acid, resulting in loss of effectiveness. It was shown that esters, including triflate esters, which are short-lived intermediates formed in the reaction of alkenes with triflic acid, play an important role in alkylate selectivity.\textsuperscript{156} Intermediates such as surface alkoxydes formed between an alkene and an acid site are believed to passivate solid acids.

Acidity-dependence studies were also made using triflic acid modified with trifluoroacetic acid (TFA) and water in the range of acidity between $H_0 = -10.1$ and $-14.1$.\textsuperscript{157} The best alkylation conditions were found to be at an acid strength of about $H_0 = -10.7$, giving calculated research octane numbers of 89.1 (triflic acid–TFA) and 91.3 (triflic acid–water). Alkylation in liquid CO\textsubscript{2} with weak acids shows a decrease in alkylate quality because CO\textsubscript{2} acts as a competing weak base and decreases acidity.\textsuperscript{158} The heavy ends—that is, C\textsubscript{9} and higher fractions—formed by oligomerization, in turn, increase (Scheme 5.23). With the stronger acids (triflic acid, HF), however, higher optimum research octane numbers were obtained than in the neat acids (95.6 for HF and 88.0 for triflic acid). Moreover, these reactions required less acid catalyst and afforded increased selectivities to trimethylpentanes.

Pyridinium poly(hydrogen fluoride) (PPHF), which serves as an HF equivalent catalyst with decreased volatility,\textsuperscript{159} showed similar characteristics in liquid CO\textsubscript{2}.\textsuperscript{158} Other liquid amine poly(hydrogen fluoride) complexes with high (22:1) HF/amine ratios are also effective catalysts in the alkylation of isobutane with butenes and, at the same time, also act as ionic liquid solvents.\textsuperscript{160} Likewise the solid poly(ethyleneimine)/HF and poly(4-vinylpyridinium)/HF (1:24) complexes have proved to be efficient catalysts affording excellent yields of high-octane alkylates with research octane numbers up to 94.

Silica-supported triflic acid catalysts were prepared by various methods (treatment of silica with triflic acid at 150°C or adsorption of the acid from solutions in trifluoroacetic acid or Freon-113) and tested in the isobutane–1-butene alkylation.\textsuperscript{161} All catalysts showed high and stable activity (near-complete conversion at room temperature in a continuous flow reactor at 22 bar) and high selectivity to form saturated C\textsubscript{8} isomers (up to 99%) and isomeric trimethylpentanes (up to 86%). Selectivities to saturated C\textsubscript{8} isomers, however, decreased considerable with time-on-stream (79% and 80% after 24 h).

Various Nafion preparations have extensively been studied in alkane–alkene alkylations. The initial high activity of Nafion-H beads applied in isobutane–2-butene alkylation at 80°C decreased rapidly, which was attributed to coking.\textsuperscript{162} Corma and co-workers\textsuperscript{163} have studied Nafion–silica nanocomposites with 13%, 20%, and 53% loadings. They observed a lower initial activity and selectivity and faster deactivation for catalysts with the same Nafion content but with larger surface area. This was explained by the fact that in nanocomposites with higher surface area the interaction between silanol groups of silica and sulfonic acid groups of highly dispersed Nafion particles is more extensive. A charge transfer may occur, resulting in decreased acidity and, consequently, lower catalytic activity. This may be significant for a demanding reaction such as alkane–alkene alkylation. Because of this leveling effect,\textsuperscript{164} the catalytic performance of a 16% Nafion–SiO\textsubscript{2} catalyst prepared by impregnation was similar to those of the nanocomposites.
The isobutane–1-butene alkylation was studied in dense CO\textsubscript{2} in both fixed-bed and slurry reactors.\textsuperscript{165–167} Both Nafion SAC-13 and Nafion SAC-25 exhibited steady-state conversions and selectivities for 50 h. Enhanced C\textsubscript{8} alkylate selectivity could be achieved at near total butene conversion. The maximum value attained, however, was only about 40%. The higher effective alkylation rate constant for SAC-25 compared to SAC-13 indicates improved accessibility of the acid sites. Nafion SAC-13 and SAC-25 applied in a study to test the effect of supercritical fluids on alkylation exhibited only modest activities.\textsuperscript{168}

A comparative study of nanocomposites (16% Nafion–silica and commercial SAC-13) has been performed by Hoelderich and co-workers\textsuperscript{169} in the alkylation of isobutane and Raffinate II. Raffinate II, the remaining C\textsubscript{4} cut of a stream cracker effluent after removal of dienes, isobutane, propane, and propene, contains butane, isobutylene, and butenes as main components. High conversion with a selectivity of 62\% to isooctane was found for Nafion SAC-13 (batch reactor, 80°C). Both the quality of the product and the activity of the catalysts, however, decrease rapidly due to isomerization and oligomerization. Treating under reflux, the deactivated catalysts in acetone followed by a further treatment with aqueous hydrogen peroxide (80°C, 2 h), however, restores the activity.

The protolytic condensation of methane in Magic Acid solution at 60°C is evidenced by the formation of higher alkyl cations such as tert-butyl and tert-hexyl cations\textsuperscript{23,25,170} (Scheme 5.24).

\]

\textbf{Scheme 5.24}

It is not necessary to assume a complete cleavage of methonium ion [CH\textsubscript{3}]\textsuperscript{+}\textsuperscript{38} to a free, energetically unfavorable methyl cation. The carbon–carbon bond formation can indeed be visualized as the C–H bond of methane reacting with the developing methyl cation [Eq. (5.68)].

\end{align*}
\]

\textbf{Eq. (5.68)}
In order to overcome unfavorable thermodynamics, hydrogen must be oxidatively removed (either by superacid or added oxidant). Considering the abundance of methane in nature, the conversion of natural gas into branched liquid hydrocarbons in the gasoline range is of immense interest.

Polycondensation of alkanes over HSO$_3$F–SbF$_5$ has also been achieved by Roberts and Calihan.$^{171}$ Several low-molecular-weight alkanes such as methane, ethane, propane, $n$-butane, and isobutane were polymerized to highly branched oily oligomers with a molecular weight range from the molecular weight of monomers to around 700. These reactions again follow the same initial protolysis of the C–H or C–C bond, which results in a very reactive carbenium ion. Similarly, the same workers$^{172}$ were able to polycondense methane with a small amount of olefin such as ethylene, propylene, butadiene, and styrene to yield oily polymethylene oligomer with a molecular weight ranging form 100 to 700.

Herlem and Jobert-Perol$^{173}$ carried out the oligocondensation of methane, ethane, and propane in HF–HSO$_3$F (1:1) by generating carbenium ions by anodic oxidation using a Pt anode. Reactions were quenched by injecting hydrogen into the high-pressure electrolysis cell. Methane gave ethane with high selectivity (90%), which is attributed to the low electrooxidation rates to ethane. Propane was formed with similar selectivity from ethane the rest being isobutane, whereas propane was transformed to isobutane (74%) and isopentane (25%). The observed high electrical yields are likely due to high local acidity around the anode.

The superelectrophilic RCOX–2AlBr$_3$ (R = Me, Pr; X = Cl, Br, I) complexes induce rapid oxidative coupling of excess C$_5$–C$_6$ cycloalkanes without solvent to form a mixture of isomeric dimethyldecalinins with high selectivities$^{174}$ [Eq. (5.69)]. Yields calculated on the superelectrophiles are near quantitative. Complexes of polyhalomethanes (CBr$_4$, CCl$_4$, CHCl$_3$) with AlX$_3$ (X = Cl, Br) have recently been shown to be equally effective.$^{175}$

\[
\begin{align*}
\text{2} & \quad \text{RCOX–2AlBr}_3 \\
\text{20°C, 1 h} & \quad \text{Me} \\
\text{Me} & \quad \text{2} \\
\text{Me} & \quad \text{Me} \\
\end{align*}
\]

\[\text{(5.69)}\]

The AcBr–2AlX$_3$ (X = Cl, Br) complexes display high activity in the alkylation of adamantane with alkanes to form polyalkylated adamantanes (C$_{11}$ $<$ C$_n$ $<$ C$_{33}$) and bisadamantylalkanes (C$_{23}$ $<$ C$_n$ $<$ C$_{50}$)$^{119}$ [Eq. (5.70)]. The suggested pathway includes the 1-adamantyl cation and alkyl cations generated by hydride removal by the superacidic complexes. The 1-adamantyl cation then alkylates alkenes equilibrating with the alkyl cations. Various transformations may follow, resulting in the formation of additional products.
5.2. ALKYLATION OF AROMATIC HYDROCARBONS

5.2.1. Alkylation with Alkenes

Cumene is industrially produced by propylating benzene over supported acidic catalysts such as phosphoric acid. On the other hand, the largest-scale single industrial alkylation process—that is, ethylation of benzene with ethylene—is still carried out to a significant degree in the liquid phase using acid catalysts; since ethylene is less polar than propylene, it requires more forcing conditions in the protolytic initiation step [Eq. (5.71)].

\[
\text{R} + \text{H}^+ \xrightarrow{\text{H}^+} \text{CH}_3\text{CH}_2\text{H}^+ \xrightarrow{\text{C}_6\text{H}_6} \text{CH}_2\text{CH}_3
\]  

(5.71)

Consequently, stronger solid acids were needed to activate the ethylation reaction. The solid acids that were available earlier exhibited only limited acidity, which was sufficient to promote the propylation of benzene with propylene at reasonable temperatures and pressures, but it was not high enough to promote ethylation of benzene with ethylene under similar conditions.

The conventional resinsulfonic acids such as sulfonated polystyrenes (Dowex-50, Amberlite IR-112, and Permutit Q) are of moderate acidity with limited thermal stability. Therefore, they can be used only to catalyze alkylation of relatively reactive aromatic compounds (like phenol) with alkenes, alcohols, and alkyl halides. Nafion-H, however, has been found to be a suitable superacid catalyst in the 110–190°C temperature range to alkylate benzene with ethylene (vide infra).\(^{176}\) Furthermore, various solid acid catalysts (ZSM-5, zeolite β, MCM-22) are applied in industrial ethylbenzene technologies in the vapor phase.\(^ {177}\)

In addition to alkenes, functionalized alkenes can also be used as alkylation agents. Koltunov, Walspurger, and Sommer,\(^ {178,179}\) have reported the alkylation of benzene with \(\alpha,\beta\)-unsaturated carboxamides in the presence of excess aluminum chloride [Eq. (5.72)]. The reaction takes place under mild conditions and gives the products in near-quantitative yields. Results with ortho-dichlorobenzene and triflic acid are usually inferior. Triflic acid, however, can catalyze similar reactions of cyclic and open-chain unsaturated amines with benzene to give phenylalkylamines in excellent yields.\(^ {180}\) The transformations are interpreted by invoking the involvement of dicationic intermediates 39 and 40.
Shudo and co-workers\textsuperscript{181} have studied the effect of various functional groups on the reactivity of the carbon–carbon double bond in alkylations. $\alpha,\beta$-Unsaturated carbonyl compounds react with benzene under superacidic conditions to yield the corresponding ketones [Eq. (5.73)]. The primary alkylation products, however, may undergo cyclization ($R = H, Me$) to give phenylindene derivatives. The parent compound cinnamaldehyde is almost unreactive in triflic acid (6\% of 3-phenylindene), but ketones react readily. Higher yields were found in the presence of triflic acid–SbF\textsubscript{5}. The corresponding oximes are more reactive to give products in very high yields (65–99\%).

Superelectrophilic dicationic species 41, 42, and 43 were suggested to be involved in the alkylation steps of the above transformations.
Nitroalkenes react with benzene derivatives at low temperature in triflic acid to afford α-aryl ketones after quenching with methanol\cite{182,183} \text{[Eq. (5.74)]}. At higher temperature the O-protonated oxime intermediate may react further to yield 4H-1,2-benzoxazines (see Section 5.14.1.3). α-Nitrocarbonyl compounds show similar characteristics as alkylating agents to yield oximes with the involvement of the tricationic intermediate 44.\cite{181}

\[
\begin{align*}
\text{H} & \text{NO}_2 + \text{Ar} \rightarrow \text{Ar} \text{H} \text{N} \text{HO} \text{OH} \\
\text{H} & \text{R}_1 \text{R} \text{R}_2 + \text{CF}_3 \text{SO}_3 \text{H} \rightarrow \text{Ar} \text{H} \text{R}_1 \text{R} \text{R}_2 \text{NC} \\
\text{R} = \text{Me, Et, Ph}, & \text{R}_2 = \text{H, Ph} \\
\text{R} = \text{R}_1 = \text{(CH}_2\text{)}_4 & \\
\text{R}_2 = \text{Me, MeO, Cl} & \\
\text{R}_3 = \text{H, 4-Me, 4-MeO} & \\
\text{40°C} & \text{1 min–2 h} \\
\text{MeOH} & \text{37-93% yield}
\end{align*}
\]

\text{(5.74)}

Shudo and co-workers\cite{181} have made the general observation that electron-withdrawing substituents on the cationic center increase reactivity toward benzene by increasing electrophilicity. Reactive carbenium ions may be described by the general formula 45, where X represents genuine electron-withdrawing groups such as carbenium, oxonium, and ammonium.

\[
\begin{align*}
\text{C} & \text{X} + \text{C} \\
\text{X} = & \text{N} \text{HO} \text{H} \text{N} \text{HO} \text{OH} \\
& \text{H} \text{N} \text{HO} \text{OH} \text{N} \text{HO} \text{OH} \\
& \text{F} \text{C} \text{F} \text{C} \text{F} \text{C}
\end{align*}
\]

Klumpp and co-workers have shown that phosphonium\cite{184} or ammonium\cite{185} groups can also dramatically enhance the reactivities of adjacent electrophilic centers and, consequently, the alkylating ability of alkenes (and carbonyl compounds). For example, they have prepared aryl-substituted piperidines in high yields (60–99%) by reacting 1,2,3,6-tetrahydropyridines with benzene in triflic acid.\cite{186} The alkylation is regioselective: the parent compound and N-methyl- and 2,2,6,6-tetramethyl-substituted derivatives give 4-phenyl-substituted products exclusively, whereas 3-substituted N-methyl compounds afford 3-phenyl-substituted derivatives. This observation and reactivities of substituted benzenes indicate the possible involvement of 1,4-dicationic and 1,3-dicationic species 46 and 47, respectively, as the most stable intermediates.
The AlCl$_3$–graphite and graphite intercalates of related Lewis acid halides have been tested as solid catalysts for the gas-phase alkylation of aromatic hydrocarbons.\textsuperscript{112,187} The catalytic activity of intercalation compounds of AlCl$_3$, AlBr$_3$, and FeCl$_3$ in graphite was measured toward two model reactions, the alkylation of benzene with ethylene and propylene [Eq. (5.75)] and the transethylation of benzene with diethylbenzene. The ethylation of benzene with ethylene proceeded to give high initial yield at temperatures as low as 125°C (Table 5.9) when the intercalated Lewis acid halide was AlCl$_3$. The initial yield is lower when AlBr$_3$ is used and very low when SbF$_5$ or FeCl$_3$ are intercalated in the graphite layers. The same results were observed when these catalysts were used to induce transethylation of benzene with diethylbenzene (see Section 5.2.6).

\[
\text{alkylation of aromatic hydrocarbons} \quad \text{alkylation of aromatic hydrocarbons}
\]

Although in the case of relatively active catalysts (AlCl$_3$–graphite and AlBr$_3$–graphite) the initial conversions were high, their activity declined rapidly with the

\]
time-on-stream. The catalysts were completely deactivated after a period of 6–8 h. There are two possible reasons for the loss in catalytic activity of these systems: (i) possible hydrolysis by traces of moisture present in the feed and (ii) leaching of the metal halide from the graphite layers by the feed.

Lalancette et al.\textsuperscript{188} indicated that intercalation process can be carried out in CCl\textsubscript{4} solution only if the Lewis acid halide is slightly soluble in the solvent. Therefore, AlCl\textsubscript{3} is probably eluted from the graphite by the feed. The rate of this process will increase with the increase in temperature, which increases the vapor pressure of Lewis acid halide. Hence, there are several drawbacks in using these graphite intercalates.

On the other hand, the Nafion resin in its acidic form (Nafion-H) shows high activity in a variety of electrophilic reactions. Gas-phase alkylation of benzene with ethylene and propylene in a flow system proceeds at temperatures as low as 110°C over Nafion-H (Table 5.10).

In the alkylation of ethylbenzene with ethylene, with conventional acid catalysts under usual conditions, sec-butylbenzene is a byproduct. sec-Butylbenzene was detected when the reaction was carried out over catalysts such as supported phosphoric acid,\textsuperscript{189} ferric phosphate,\textsuperscript{189} or AlCl\textsubscript{3}–NiO–SiO\textsubscript{2}.\textsuperscript{190} When Nafion-H or AlCl\textsubscript{3} are used, no such byproduct is detected, probably due to fast dealkylation of sec-butylbenzene under the more acidic conditions.

The high acidity of the Nafion-H catalyst is further demonstrated by its ability to promote both polyalkylation and isomerization. In reaction between benzene and ethylene at 190°C, 20% of the alkylated products are diethylbenzenes.\textsuperscript{187} The isomer distribution of the diethylbenzenes is 1% of the ortho, 75% of the meta, and 24% of the para isomers. This composition is very close to the equilibrium composition of diethylbenzenes determined in solution chemistry with AlCl\textsubscript{3} catalyst and indicates that the reaction is thermodynamically controlled.

Nafion–silica nanocomposite catalysts and silicas modified with superacidic surface functions (see Section 2.4.2.2) developed recently have been tested in

Table 5.10. Alkylation of Benzene with Alkenes over Nafion-H Catalyst\textsuperscript{187}
Friedel–Crafts alkylation of aromatics with various alkenes. Alkylation of benzene with 1-dodecene to form linear alkylbenzenes (LABs) is of particular interest because LABs play a key role in the industrial production of surfactants. The preferred product is 2-phenyldodecane, and a high linearity of all alkylated products is also required. A nanocomposite sample made by the hydrolysis of sodium silicate gave better than 95% LAB selectivity at 99% conversion, whereas lower conversion was measured over silica with anchored perfluorinated sulfonic acid sites (structure 48, Figure 5.15). At low conversion, selectivity of 2-phenyldodecane was 28%, which is significantly higher than values for the industrial HF process (15–18%). Another significant advantage of nanocomposites is the very low selectivity for the undesirable branched alkylbenzenes, which is attributed to the low activity of Nafion–silica to catalyze skeletal isomerization. Superior catalyst performance was observed for the type 2 catalyst in transalkylation as well.

An alkene mixture of industrial source (equal amounts of C₉–C₁₃ alkenes and alkanes) was used in the alkylation of benzene on three Nafion–silica catalysts with 5%, 13%, and 20% loadings. 20% Nafion–silica showed high and stable activity and its performance exceeded that of a Y-zeolite-based material. The selectivity to 2-phenylalkanes (25%) was higher than in the Detal process using fluorinated silica–alumina but decreased somewhat with increasing Nafion content.

Harmer et al. used 1,1,2,2-tetrafluoroethanesulfonic acid in the alkylation of para-xylene with 1-dodecene. The silica-embedded catalyst prepared by the sol–gel method showed much higher activity than the neat acid (almost complete conversion in 15 min at 100°C over the sol–gel-derived material versus 10% conversion, using the same molar amounts of acid). Practically no leaching was detected and the catalyst could be recycled with a slight decrease in conversion. It is in sharp contrast with silica-supported triflic acid, which showed much lower activity due to the loss of volatile triflic acid.

Superelectrophilic dication have been observed by Coustard, who used ¹H and ¹³C NMR spectroscopy in triflic acid at low temperature (Scheme 5.25). They
were slowly transformed into ions 51, which alkylated benzene to yield aryliminohydroxyimino derivatives. The 4-MeO-substituted compound gave the cyclialkylated product as well.

### 5.2.2. Alkylation with Alcohols and Cyclic Ethers

Data for the use of alcohols as alkylating agents in superacids are scarce. A study of the alkylation of phenol and naphthols with tert-butyl alcohol has shown that triflic acid adsorbed on aminopropyl-modified silica is the most selective to yield monoalkylated products compared to solid acids (triflates immobilized in silica). Sarca and Laali have used triflic acid in butylmethylimidazolium hexafluorophosphate [BMIM][PF$_6$] ionic liquid for the benzylation of various arenes with benzyl alcohol [Eq. (5.76)]. When compared with Yb(OTf)$_3$, triflic acid proved to be a better catalyst showing higher selectivity (less dibenzyl ether byproduct) by exhibiting similar activity (typically complete conversion). Of the isomeric products, para isomers dominate. Experimental observations indicate that dibenzyl ether originates from less complete protonation of benzyl alcohol and, consequently, serves as a competing nucleophile. Both substrate selectivity ($k_T/k_B$) and positional selectivity (ortho/para ratio) found in competitive benzylation with a benzene–toluene mixture (1:1 molar ratio) are similar to those determined in earlier studies, indicating that the nature of the electrophile is not affected in the ionic liquid.
Prakash, Bach, and co-workers\textsuperscript{200} have subjected a series of chiral benzylic alcohols to S\textsubscript{N}1-type displacement reaction with aromatics catalyzed by triflic acid or HBF\textsubscript{4}-OEt\textsubscript{2}. Under optimized conditions the alcohols give alkylated products in high yield with high facial diastereoselectivity [Eq. (5.77)]. The enantiomerically pure alcohol (R = H) showed no significant racemization. NMR characterization of the long-lived benzylic cation \textsuperscript{52} generated under superacidic conditions (SbF\textsubscript{5}–SO\textsubscript{2}Cl\textsubscript{2}, −70°C) allowed the authors to demonstrate that such conformationally restricted carbocationic intermediates are responsible for the high stereoselectivity of alkylation observed.

Triflic acid is also efficient in the alkylation of electron-rich aromatics (anisole, 1,3-dimethoxybenzene, 2-methylfuran, pyrrole, benzofuran, indole) with secondary benzylic alcohols and 3-phenylallyl alcohols\textsuperscript{201} [Eq. (5.78)]. Suprisingly, however, the primary products (with the exception of the 4-methylphenyl-substituted compound) undergo rearrangement upon prolonged treatment to yield alkenes
selectively with the indicated stereochemistry [Eq. (5.78)]. The possible involvement of dicationic intermediates is suggested.

\[ \text{ArH, CF}_3\text{SO}_2\text{H} \quad \text{RT, 1–2 h} \]

\[ \text{Ar} = \text{benzene, toluene, 4-halobenzenes} \quad 78–82\% \]

\[ \text{CF}_3\text{SO}_3\text{H} \quad \text{RT, 12–24 h} \]

\[ \text{50–67\%} \]

(5.78)

Kotsuki et al.\textsuperscript{203} have reported high yields of alkylated products formed in the presence of triflic acid using cyclohexyl methanesulfonate [Eq. (5.79)]. Similar performance was found for mesitylene, durene, and naphthalene, as well as for other secondary alcohol methanesulfonates.

\[ \text{R} = \text{H, Me, MeO} \quad 56–94\% \text{ yield} \]

\[ \text{R}' = \text{H, Me} \]

\[ \text{CF}_3\text{SO}_3\text{H} \quad \text{80°C, 0.2–2 h} \]

\[ \text{56–94\% yield} \]

(5.79)

Epoxides are well-known carbon electrophiles and proved to be useful reagents in alkylations. A systematic study\textsuperscript{204} with oxetanes, oxiranes, and oxolanes in the presence of triflic acid showed that various alkylated products are formed, but with low selectivities due to multiple alkylations and cyclialkylation. Methyl (R)-glycidate, in turn, has been shown to react with electron-rich arenes in triflic acid to give α-hydox-β-arylpropanoates with high stereospecificity\textsuperscript{205} [Eq. (5.80)]. The high regioselectivity was attributed to the selective ring opening to yield the intermediate cation \textbf{54}, and dication \textbf{55} was also postulated. In a recent similar study,\textsuperscript{206} the facile synthesis of 1-trifluoromethyl- and 1,1-bis(trifluoromethyl)-2-arylethanols has been reported [Eq. (5.81)]. Observations with respect to reactivities and selectivities were well demonstrated through DFT calculations (B3LYP/6-31G* level).
When olefins are used as alkylating agents, the catalytic activity of Nafion-H slowly decreases, most probably due to some polymerization on the surface, which deactivates the catalytic sites. The activity decreases faster when more reactive branched alkenes are used. The use of alcohols instead of olefins as the alkylating agents improves the lifetime of the catalyst. With alcohols, no ready polymerization takes place, since water formed as byproduct inhibits polymerization of any olefin formed (by dehydration) but does not affect the acidity of the catalyst at the reaction temperatures.

Reaction of alcohols with benzene over Nafion-H catalysts gave the corresponding alkylbenzenes (Table 5.11). When n-propyl alcohol was the alkylating agent, no n-propylbenzene was detected, and the only product obtained was cumene. This indicates the intermediacy of the isopropyl cation in the alkylation process.

The alkylation of aromatic hydrocarbons with methyl alcohol over Nafion-H catalysts, including the mechanistic aspects, has been studied in detail. The degree of conversion of methyl alcohol was much dependent on the nucleophilic reactivity of the aromatic hydrocarbon. For example, the reactivity of isomeric xylenes was higher than that of toluene or benzene.

A study of the temperature dependence of the reaction between toluene and methyl alcohol showed a substantial increase in xylene formation as the temperature was increased. However, the overall yield of xylene at 209°C was lower than that expected from extrapolation of data obtained at lower temperatures. This is probably
due to the increasing thermal instability of Nafion-H at temperatures around and above 200°C and hence its reduced activity.

Yields and conversion of methyl alcohol were much higher when the aromatic substrate was phenol or anisole and their derivatives208 (Table 5.12). In recent studies, various degrees of selectivity were reported in the gas-phase methylation of phenol toward the ortho substitution, using catalysts such as Al2O3,209–211 TiO2,212 ZnO, Fe2O3,213,214 ZnO·MO (M = Cu, Ba, Ca, Co, Mn, Mg, Ni),215 MgO alone,216 or mixed with oxides of Mn, Cu, Sn, Bi, Pb or Cr217 at temperatures ranging from 250°C to 400°C. Unlike these examples, the selectivity toward ortho methylation when using Nafion-H as catalyst is somewhat lower,208 probably due to the absence of basic sites on this solid catalyst.

In gas-phase methylation reactions over Nafion-H using methyl alcohol as the alkylation agent, the consumption of methyl alcohol was higher than that calculated by product analysis.207,208 This is due to the formation of dimethyl ether as the byproduct [Eq. (5.82)]. Indeed, when neat methyl alcohol is passed over Nafion-H catalyst at temperatures over 150°C, dimethyl ether is the only product formed quantitatively with water as the byproduct.218

aExcluding starting material.
Therefore, studies were also carried out using dimethyl ether as the methylating agent over Nafion-H catalyst. The initial conversions were similar to those obtained with methyl alcohol as the methylating agent. However, the reactivity of the catalyst was found to decrease sharply with time probably due to the increased esterification of the acidic sites of the solid catalyst.\textsuperscript{207} The reactivity of the catalyst could be, however, readily regenerated by passing steam over it at 180°C for 1 h. In general, it appears that the presence of water vapor (i.e., steam) in the systems catalyzed by Nafion-H does not reduce the activity of the catalyst. In cases where polymerization and other possible side reactions would lead to the deactivation of the catalyst, the presence of water helps to maintain the catalytic activity of Nafion-H catalyst. For example, when benzene was alkylated by dimethyl ether over Nafion-H, the use of benzene saturated with water slowed down the deactivation of the catalyst considerably.

Olah and co-workers\textsuperscript{219} have applied Nafion-H in the benzylation of benzene with benzyl alcohols [Eq. (5.83)] and also reported the reaction of benzyl alcohol with substituted aromatics (toluene, xylenes, mesitylene) to yield diphenylmethanes. The reaction is performed under mild conditions and produces the corresponding dibenzyl ethers as byproducts (2–22\%). The substrate and positional selectivity in competitive benzylation of benzene and toluene (1:1 molar ratio) was found to be almost the same as observed in solution-phase Friedel–Crafts benzylation with benzyl chloride (AlCl\textsubscript{3}–CH\textsubscript{3}NO\textsubscript{2}). Cyclic products 56 and 57 resulting from cyclialkylation were isolated when Nafion-H-catalyzed benzylation was applied to 2-(hydroxymethyl) diphenylmethane and 3,4-dimethoxybenzyl alcohol, respectively.
Friedel–Crafts alkylation of benzene,\textsuperscript{220,221} toluene,\textsuperscript{222} para-xylene,\textsuperscript{220} and naphthalene\textsuperscript{223} with benzyl alcohols have been studied over Nafion–silica nano-composite catalysts, including the kinetics of alkylation.\textsuperscript{221,223} In most cases, 13\% Nafion–silica showed the highest activity, testifying again to the much higher accessibility of the active sites. Complete conversion of para-xylene was found in the presence of triflic acid, and it was the only reaction when ether formation as side reaction did not occur.

The isopropylation of meta-cresol with propylene and isopropyl alcohol\textsuperscript{224,225} and anisole with propan-1-ol\textsuperscript{226} [Eq. (5.84)] was studied in supercritical CO\textsubscript{2} in a continuous flow reactor over Nafion SAC-13 and, for comparison, other organic-based and inorganic solid acids. The optimal reaction temperature for Nafion SAC-13 was found to be 200–250°C. This temperature range is significantly higher than those for organic-based catalysts, which lost sulfonic acid groups at these high temperatures. Selectivity toward monoalkylated products, however, decreases with increasing temperature.

![Chemical Reaction Image](image)

Fujiwara et al.\textsuperscript{227} tested a nanocomposite material having Nafion immobilized in MCM-41 mesoporous silica in Friedel–Crafts alkylations with benzyl alcohol. Whereas Nafion–MCM-41 showed lower activity in the alkylation of toluene than 13\% Nafion SAC-13 under identical conditions, it exhibited increased activity when used in the alkylation of para-xylene.

In 1976, Lalancette et al. studied\textsuperscript{228} the catalytic activity of graphite intercalated AlCl\textsubscript{3} and compared it with neat AlCl\textsubscript{3} in solution-phase alkylations. Whereas the rate of alkylation slowed down using the intercalated catalyst, a higher selectivity toward monoalkylation was found (Table 5.13).

### 5.2.3. Alkylation with Alkyl Halides

Jouannetaud and co-workers\textsuperscript{229} have explored electrophilic trifluoromethylation under superacidic conditions of aniline derivatives\textsuperscript{229} and N-heterocycles. Methyl-substituted anilines and substituted acetanilides [Eq. (5.85)] react with the “CCl\textsubscript{3}” cation generated from CCl\textsubscript{4} in HF–SbF\textsubscript{5} followed by fluorination to yield the corresponding trifluoromethyl derivatives. Under similar conditions, indolines are transformed to the 6-trifluoromethyl derivatives, whereas substituted indoles yield 5-trifluoromethyl derivatives.\textsuperscript{230}
Olah et al.\textsuperscript{231} have used boron tris(triflate) [B(OSO\textsubscript{2}CF\textsubscript{3})\textsubscript{3} or B(OTf)\textsubscript{3}] in Friedel–Crafts alkylation with alkyl halides to give alkylated arenes in low yields (Table 5.14). It is known that alkylation of alkylbenzenes promoted by Lewis acids, in general, leads to the formation of increased amounts of meta isomers. Indeed, high, sometimes exclusive formation of the meta isomer is observed with the use of B(OTf)\textsubscript{3}. In the case of ethyl chloride, for example, high initial meta selectivity is found, which changes after prolonged reaction approaching the equilibrium distribution.

High meta selectivities can be explained by intramolecular isomerization within the arenium ion intermediates to the most stable 1,3-disubstituted isomeric ethyltoluene ion [Eq. (5.86)]. Isomerization is induced by the very strong conjugate acid formed between B(OTf)\textsubscript{3} and HF or HCl generated during alkylation from the corresponding alkyl halides. Ethyltoluene isomers were found in independent experiments to readily undergo isomerization with B(OTf)\textsubscript{3} in dichloromethane to give equilibrium isomer composition. Alkylation with isopropyl chloride shows that isomerization is more pronounced in the less coordinating dichloromethane solvent than in nitromethane. In tert-butylation with tert-butyl fluoride the high initial meta isomer content rapidly decreases. This is accounted for by facile de-tert-butylation with excess toluene yielding predominantly para-tert-butyltoluene (kinetic product). After prolonged reaction the quantity of the meta product increases again due to the thermodynamically directed intramolecular isomerization.

\begin{equation}
\begin{align*}
\text{Me} & \quad \text{H} & \quad \text{Me} & \quad \text{Et} \\
\text{Et} & \quad \text{H} & \quad \text{H} & \quad \text{Et}
\end{align*}
\end{equation}

Boron tris(triflate) has also been tested in the adamantylation of benzene and toluene with 1-haloadamantanes [Eq. (5.87)] and 2-haloadamantanes.\textsuperscript{232} B(OTf)\textsubscript{3} is a highly active catalyst to promote the transformation in very short time under mild conditions to yield isomeric aryladamantanes and adamantane byproduct (Table 5.15). Of the isomeric 1-tolyladamantanes, 1-meta-tolyladamantane predominates, whereas the para isomer is the main product of the 2-tolyladamantanes. The ortho isomers were

not detected, which is attributed to the significant steric hindrance with the tertiary bridgehead system and possible fast isomerization.

\[ \text{R} + \text{X} \xrightarrow{\text{catalyst}} \text{R} + \text{X} \]

\( R = \text{H, Me} \)

\( X = \text{F, Cl, Br} \)

The relative reactivities of benzene and toluene were studied in competitive reactions with benzene–toluene mixture. Isomeric tolyladamantanes, in this case, was formed in much lower yield (Table 5.16); that is, low substrate selectivity \( (k_T/k_B = 0.5–4.8) \) prevails. These data, however, are obscured by significant disproportionation indicated by the high amounts of adamantane detected. Furthermore, various isomerizations resulting in rather varied isomer distributions were also observed. In the isomeric tertiary and secondary substituted phenyladamantanes, 1-phenyladamantane is highly favored. Interestingly, 1-adamantanoyl chloride was also found to give aryladamantane products. 1-Adamantanoyl chloride readily ionizes with the strong Lewis acid B(OTf)\(_3\) and, then, the formed adamantanoyle cation loses CO to form the 1-adamantyl cation.

Formation of the 2-substituted aryldamantane products can be accounted for by an intermolecular isomerization process (Scheme 5.26). It requires the formation of

\[ \text{H}^+ \xrightarrow{\text{intermolecular hydride transfer}} \]

adamantane through hydride transfer followed by the formation of isomeric 1- and 2-adamantyl cations, which alkylate the arene formed in the first step. Isomerization of meta- and para-tolyladamantes, in turn, is interpreted as intramolecular 1,2-migration processes (Scheme 5.27).

Olah and et al.\textsuperscript{233} have studied the alkylation of aromatics with 1-chloronorbornane, 3-halonoradamantane, and fluorocubane in the presence of AlCl\textsubscript{3} and BF\textsubscript{3}. Backside S\textsubscript{N}2-type displacement at bridgehead positions is not possible. Consequently, Friedel–Crafts alkylation with these halides must involve strongly polarized bridgehead halide–Lewis acid complexes in equilibrium with their energetic, reactive carbocations. Since the strained bridgehead centers cannot flatten out, the carbocationic center is \textit{sp}\textsuperscript{3}-hybridized and the empty orbital of these carbocations is of \textit{sp}\textsuperscript{3} nature (58–60). The reactive 1-norbornyl, 3-noradamantyl, and cubyl cations could not be observed under stable ion conditions by NMR spectroscopy at low temperature (SbF\textsubscript{5}–SO\textsubscript{2}ClF solution, −78°C).
Laali et al.\textsuperscript{234} have developed a method to the highly selective \textit{para}-adamantylation of arenes (toluene, ethylbenzene, anisole) with haloadamantanes (1-chloro- and 1-bromoadamantane, 1-bromo-3,5,7-trimethyladamantane) and 1-adamantanol promoted by triflic acid in butylmethylimidazolium triflate [BMIM][OTf] ionic liquid. In contrast to reactions run in 1,2-dichloroethane, little or no adamantane byproduct was detected in [BMIM][OTf]. Furthermore, no isomerization of \textit{para}-tolyladamantane was observed supporting the intramolecular nature of the formation of \textit{meta} isomers. In competitive experiments with benzene–toluene mixture (1:1 molar ratio), high substrate selectivities were found ($k_T/k_B = 16–17$) irrespective of the alkylating agent. This is in sharp contrast to values about unity measured in 1,2-dichloroethane.

Satisfactory results were obtained in the Nafion-H-catalyzed gas-phase alkylation of aromatic hydrocarbons with alkyl halides\textsuperscript{235} [Eq. (5.88)]. Alkyl halides are reactive Friedel–Crafts alkylating agents and give high conversions when alkylating benzene in the gas phase over Nafion-H catalyst. For example, in the alkylation of benzene with isopropyl chloride, conversions as high as 87\% were achieved (Table 5.17, run 11). Conversions, however, were temperature and contact time dependent (Table 5.17).

$$\text{ArH} + \text{RX} \xrightarrow{\text{Nafion-H}} \text{ArR} + \text{HX}$$

The selectivity of the Nafion-H catalyst for monoalkylation has been found to be generally high. With a molar ratio of benzene:isopropyl chloride being 5:1, about 94\% of the alkylate is monoalkylbenzene. This result is comparable to the highly selective monoalkylation reaction reported by Langlois.\textsuperscript{236} They alkylated benzene with propylene (5.2:1 molar ratio) over H\textsubscript{3}PO\textsubscript{4}-quartz catalyst at $\sim$200\degree C and obtained cumene in 95\% yield.

The results obtained in the gas-phase isopropylation of various aromatic hydrocarbons with isopropyl chloride over Nafion-H catalyst showed only a relatively small variation of reactivity in going from fluorobenzene to xylenes.\textsuperscript{235} Therefore, it has been assumed that the reaction rate is controlled by the formation of a reactive electrophilic intermediate (possibly, protonated alkyl halide 61, or some form of incipient alkyl cation) rather than by $\sigma$-complex formation between the electrophile and the aromatic nucleus [Eq. (5.89)].

$$\text{R'} - \text{C} - \text{X} \rightleftharpoons \text{R'} - \text{C}^+ - \text{X} - \text{H} \rightleftharpoons \text{R'} - \text{C}^+ \rightleftharpoons \text{HX}$$

The relatively minor differences observed in the degree of conversion in the reaction of various aromatic hydrocarbons with isopropyl chloride over Nafion-H are

$^b$2 g Nafion-H was used.

$^c$Benzene:isoPrCl = 5:1.

$^d$Benzene:isoPrCl = 5:4.
explained by the possibility of some dealkylation (i.e., reverse reaction). Dealkylation reactions occur as a competitive process to the alkylation process. The more nucleophilic is the alkylated aromatic product, the higher the rate of dealkylation reaction.

Besides the advantage of their high reactivity toward alkylation reactions, primary and secondary alkyl halides show little tendency for dehydrohalogenation in Nafion-H-catalyzed gas-phase reactions. Although a minor amount of olefin is reported to be formed, no polymer formation was observed on the catalyst. As a result, the catalytic activity of Nafion-H stays constant over prolonged on-stream periods.

Benzylation of various aromatics with benzyl chloride also proceeds smoothly over 13% Nafion–silica to afford diphenylmethane derivatives in high yields (Table 5.18). Although deactivated aromatics (nitrobenzene, methyl benzoate) gave low (<10%) yields, chlorobenzene reacted readily with complete conversion similar to naphthalene. Furthermore, the catalyst, after recovery, exhibited the same activity.

Olah et al. have performed a comparative study of the adamantylation of substituted benzenes with 1-bromoadamantane [see Eq. (5.87)] using various Nafion preparations and higher perfluoroalkanesulfonic acids supported on zeolite HY. Nafion-H and Nafion–silica nanocomposite exhibited high activity in the adamantylation of bromobenzene and toluene, resulting in the formation of the para isomer as the main alkylated product (Table 5.19). Exclusive formation of the para isomer was observed in the adamantylation of phenol, anisole, and fluorobenzene over Nafion-H at complete conversion. tert-Butylbenzene, in turn, gave only byproducts. Among these, 1-phenyladamantane was the only adamantylated product, which indicates the facile de-tert-butylation of the intermediate carbocation.

In a similar study, Nafion-H beads, 10% Nafion-H on silica, and 13% Nafion–silica were compared in the adamantylation of toluene with 1-bromoadamantane. 13% Nafion–silica nanocomposite exhibited the highest activity and showed a change in the isomeric ratio of the two alkylated products; the para/meta ratio shifted to lower values in prolonged reaction (Table 5.20). Acidity is known to exert a significant influence on

regioselectivity. In this case, after complete conversion the kinetic distribution (high excess of the para isomer) changed to the thermodynamic distribution (increasing amount of the meta isomer) with increasing reaction time over the nanocomposite catalyst with highly accessible acid sites. As it was pointed out, such isomerization takes place within the para-adamantylated arenium ion intermediate (Scheme 5.27).

5.2.4. Alkylation with Carbonyl Compounds and Derivatives

Carbonyl compounds, particularly aromatic aldehydes, when activated with electrophilic catalysts, can also react with aromatics. The process is often called condensation or reductive alkylation, but it is actually a multistep Friedel–Crafts alkylation reaction.

Olah et al. and Shudo and co-workers have shown that benzaldehyde reacts with benzene in various superacidic systems [triflic acid, triflic acid–SbF5, Table 5.20. Adamantylation of Toluene over Various Nafion Catalysts

Reactions conditions: 5 ml of toluene, 1 mmol of 1-bromoadamantane, 0.2 g of catalyst, 111°C. \(\text{Rate}^a\) Initial reaction rate, mmol (gcat min\(^{-1}\)).
CF₃SO₂H⁺B(OSO₂CF₃)₄⁻] to give triphenylmethane (Scheme 5.28). Experimental evidence supports the involvement diprotonated benzaldehyde in the reaction. Calculations showed (MP2/6-31G* // MP2/6-31G* + ZPE level) that the reactive intermediate is the O,C( aromatic)-diprotonated dication 62 and not the O,O-diprotonated 63 dication, which is less stable by 20.6 kcal mol⁻¹.

In a subsequent study, Shudo and co-workers showed that benzaldehydes with electron-withdrawing groups (NO₂, CF₃) react with 2 equivalents of benzene in the presence of triflic acid to give substituted triphenylmethanes in good yields [Eq. (5.90)]. They also observed that para-fluorobenzaldehyde and biphenyl-4-carboxaldehyde yield diphenylmethane and triphenylmethanol under similar conditions, and the same products were also isolated in the reaction of triphenylmethane (Scheme 5.29).
Product formation was interpreted in terms of transalkylation of substituted triphenylmethanes. Protonation at the ipso position of the substituted phenyl ring to form arenium ion 64 followed by the C—C bond breaking yields the diphenylmethyl cation, which alkylates benzene or is stabilized by hydride transfer (Scheme 5.30). The protonated intermediate 64 is highly unstable when the ring has an electron-withdrawing substituent. Consequently, its transformation is extremely slow and the primary product triphenylmethane can be isolated.

Fukuzawa et al. used 2-phenyl-1,3-dioxane to benzylate a variety of arenes [Eq. (5.91)]. Similar observations were made when substituted benzaldehydes were treated in the presence of 1,3-propanediol under identical conditions. Although 2-phenyl-1,3-dioxane gave similar results, benzaldehyde dialkylacetals in general were unreactive under similar conditions. Mechanistic studies including reaction of a labeled dioxane indicate the involvement of the alkylated intermediate 65 and product formation was interpreted via an 1,3-hydride shift.

Scheme 5.30

\[ \text{Product formation was interpreted in terms of transalkylation of substituted triphenylmethanes. Aminoacetals proved to be more reactive in triflic acid reacting with benzene at room temperature to give diphenyl-substituted products of alkylation\textsuperscript{246} [Eq. (5.92)]. Propanal acetals ($n = 1$), in general, give somewhat lower yields than acetaldehyde acetals ($n = 0$). In addition to benzene, halobenzenes also react, affording decreasing yields with decreasing nucleophilic character. Only monoprotonated species (ammonium cations) were detected in triflic acid by NMR spectroscopy. In turn, when the dioxolane derivative of 3-piperidin-1-yl-propionaldehyde was treated in triflic acid–SbF$_5$ (SO$_2$ClF solution, $-80^\circ$C), the isomeric dicationic intermediates 66 were shown to exist. This allowed the suggestion of a mechanism involving diprotonated electrophiles (carboxonium–ammonium dications).
Klumpp et al. and Sommer and co-workers have studied the alkylating ability of a variety of heterocycles with carbonyl substituents in the presence of triflic acid. Pyrazolecarboxaldehydes [Eq. (5.93)]\(^{247}\), pyridinecarboxaldehydes,\(^{248-250}\) quinolinecarboxaldehydes,\(^{251}\) piperidinones [Eq. (5.94)],\(^{252,253}\) tropinone and quinuclidone, and acetyl-substituted heteroaromatic compounds (pyridines, thiazoles, pyrazine, quinoline, and isoquinoline)\(^{254}\) proved to be highly reactive alkylating agents when reacted with benzene to give the corresponding diphenyl-substituted products in good to excellent yields.

\end{align*}
\]

\(\text{R} = \text{H, Pr, Bn, AcO, COOEt, PhCO} \quad 90-99\% \text{ yield}\)

In all cases, superelectorophilic dicationic intermediates\(^{3-5}\) were suggested to be involved in the activation of carbonyl compounds based on the observation that protonated N-heterocycles significantly enhance the reactivity of adjacent carbocationic centers. For example, cyclohexanone and acetophenone are unreactive toward benzene in triflic acid, whereas 4-piperidones\(^{252}\) and acetylpyridines\(^{254}\) react readily. Likewise, 3-pyridinecarboxaldehyde is able to alkylate deactivated aromatics such as chlorobenzene, ortho-dichlorobenzene, and nitrobenzene.\(^{248}\) Furthermore, dicationic intermediates \(67, 68, \text{ and } 69\) generated in \(\text{FSO}_3\text{H}–\text{SbF}_5–\text{SO}_2\text{ClF}\) solution have been directly observed by low-temperature NMR spectroscopy at \(-80^\circ\text{C}\).\(^{247,248,253}\) Recent computational studies have shown\(^{255}\) that the first protonation of 4-heterocyclohexanones at the carbonyl oxygen in triflic acid is exergonic (4-piperidone is an exception protonated at the N atom). The second protonation is slightly endergonic, but it is thermodynamically highly unfavorable for cyclohexanone.
Prakash, Olah, and co-workers\textsuperscript{256} have prepared Mosher’s acid analogs by the hydroxyalkylation of substituted benzenes with ethyl trifluoropyruvate [Eq. (5.95)]. Deactivated aromatics (fluorobenzene, chlorobenzene) required the use of excess triflic acid indicative of superelectrophilic activation.\textsuperscript{3–5} In contrast to these observations, Shudo and co-workers\textsuperscript{257} reported the formation gem-diphenyl-substituted ketones in the alkylation of benzene with 1,2-dicarbonyl compounds [Eq. (5.96)]. In weak acidic medium (6\% trifluoroacetic acid–94\% triflic acid), practically no reaction takes place. With increasing acidity the reaction accelerates and complete conversion is achieved in pure triflic acid, indicating the involvement of diprotonated intermediates.

\text{20°C, 5–20 h} & \rightarrow \text{46–86\% yield}
\end{align*}
\]
The use of triflic acid in the alkylation with other dicarbonyl compounds, such as isatins, parabanic acid, and ninhydrin, has also been explored. A significant acidity dependence was found in the reaction of isatin with benzene. Alkylation does not take place in the presence of trifluoroacetic acid ($H_0 = -2.7$) at $25^\circ C$ in 12 h. Adding 22% of triflic acid ($H_0 = -10.6$) brings about a 90% yield of the 3,3-diphenyloxindole, whereas complete conversion is achieved in neat triflic acid ($H_0 = -14.1$) in 8 h. Ninhydrin undergoes facile reaction with various benzene derivatives in the presence of triflic acid to yield 3-(diarylmethylene)isobenzofuranes [Eq. (5.97)], which is interpreted with the participation of the ring-opened intermediate 70. In a similar manner, alkylation in the case of $\alpha$-ketoacids is usually followed by additional reactions to results in the formation various products. For example, $\alpha$-ketosuccinic acid and $\alpha$-ketoglutaric acid give 3,3-diphenylindanone and 4,4-diphenyltetralone, respectively, as a result of dehydrative decarbonylation. Two major products were isolated in the reaction of phenylpyruvic acid as a result of secondary transformations (Scheme 5.31).
$\beta$-Ketoesters, $\beta$-ketophosphonates, and $\beta$-ketsulfones have been used to alkylate ferrocene to afford the corresponding $\beta$-ferrocenyl-$\alpha,\beta$-unsaturated derivatives in excess triflic acid$^{262,263}$ [Eq. (5.98)]. The transformations are highly stereoselective, giving exclusively the ($E$)-isomers; this was explained by the $exo$-deprotonation of carbenium ion 71a of more stable conformation. Acetals of formylphosphonates and formylsulfones react in a similar manner.

A variety of solid acids has been studied in the alkylation of benzene with formaldehyde to produce diphenylmethane$^{264}$ [Eq. (5.99)]. Aciplex–SiO$_2$ exhibited
the highest activity and gave the highest yield. Nafion SAC-13, in turn, showed the highest specific activity and highest selectivity. The difference between these two catalysts is due to the amount of acid sites. In the reaction with formalin solution, all perfluorinated resinsulfonic acid catalysts including Nafion NR50 were superior to other solid acids studied for comparison.

5.2.5. Alkylation with Acid Derivatives

The versatility of the catalytic activity of Nafion-H is well-demonstrated in the alkylation of aromatic hydrocarbons by carboxylic acid alkyl esters both in the gas phase and in heterogeneous liquid-phase reactions.\(^{265}\) Esters in the presence of conventional Lewis acid halide catalysts tend to give rise to acylation products along with alkylation products.\(^{266,267}\) The heterogeneous liquid-phase alkylation reactions have been generally carried out under reflux conditions. Two types of alkylation agent have been studied: (i) alkyl esters of carboxylic acids [Eq. (5.100)], preferentially those of oxalic acid and (ii) alkyl chloroformates [Eq. (5.101)]. The advantage of alkyl chloroformates lies primarily in their volatile byproducts (HCl and CO₂). Diethyl oxalate shows particularly good alkylating ability even under mild conditions (Table 5.21).

\[
\text{ArR'} + \text{RCOOH} \xrightarrow{\text{Nafion-H}} \text{ArR} + \text{HCl} + \text{CO}_2 \quad (5.101)
\]

The gas-phase alkylation of toluene with alkyl chloroformates over Nafion-H was also reported to be an efficient transformation. It is interesting to compare the alkylating ability of methyl chloroformate with that of methyl alcohol on toluene under similar reaction conditions. For example, a 59\% conversion with methyl chloroformate was observed,\(^{265}\) compared with 15\% conversion with methyl alcohol.

The gas-phase alkylation of toluene with dimethyl and diethyl oxalate over Nafion-H was also reported.\(^{265}\) The alkylating ability of diethyl oxalate is

comparable with that of ethyl chloroformate. However, the alkylating ability of dimethyl oxalate is lower than that of methyl chloroformate.

5.2.6. Isomerization and Transalkylation of Alkylbenzenes

When dialkylbenzenes are passed over Nafion-H at 160°C, both isomerization and disproportionation take place [Eqs. (5.102) and (5.103)]. Monoalkylbenzenes also disproportionate under these conditions\textsuperscript{268–271} [Eq. (5.104)].
As expected, the aptitude for disproportionation of the aromatic compound depends upon the nature of the alkyl group, and the order of reactivity is isopropyl > ethyl > methyl. Due to their higher nucleophilicity, polyalkylbenzenes react faster than monoalkylbenzenes. This effect is pronounced in the case of methylbenzenes. Toluene itself shows little reactivity over Nafion-H at 193°C. Diethylbenzenes react much faster than dimethylbenzenes. The rate of conversion of diethylbenzenes over Nafion-H at 193°C is \( \sim 5 \times 10^{-5} \text{ mol min}^{-1} \text{ g}^{-1} \) of catalyst.\(^{269}\) This is a low rate when compared with that using AlCl\(_3\)-HCl in the liquid phase at room temperature (\(10^{-4} \text{ mol min}^{-1} \text{ g}^{-1} \) of catalyst).\(^{272}\) However, one should bear in mind that Nafion-H is a truly insoluble heterogeneous catalyst, whereas in the case of AlCl\(_3\)-HCl a soluble complex is formed with the hydrocarbon and therefore the rates are not directly comparable. The equilibrium composition of the acid-catalyzed disproportionation of diethylbenzenes depends upon the nature of the catalyst.

The predominance of meta-diethylbenzene in the isomerization of diethylbenzenes is easily rationalized. Since isomerization reaction proceeds via arenium ion intermediates, the \( \sigma \)-complex derived from meta-diethylbenzene is the most stable one. Moreover, meta-diethylbenzene is also the most basic of the isomeric diethylbenzenes.\(^{273,274}\) Therefore, more acidic catalysts increase the amount of the meta isomer at the expense of the para (and ortho) isomers, due to the increased stability of the substrate–catalyst complex.

The AlCl\(_3\)-graphite and graphite intercalates of related Lewis acid halides have also been tested as solid catalysts for the transethylation of benzene with diethylbenzene in the gas phase\(^{112}\) [Eq. (5.105)]. The results were very similar to those observed in the ethylation of benzene (see Section 5.2.1); that is, high initial yields were found for intercalated AlCl\(_3\), lower yields were found for AlBr\(_3\), and very low yields were obtained when SbF\(_5\) was intercalated (Table 5.22).

\[
\begin{align*}
\text{C}_2\text{H}_5 + \text{C}_2\text{H}_5 & \xrightarrow{\text{catalyst}} 2 \text{C}_2\text{H}_5 \\
\text{(5.105)}
\end{align*}
\]

Nafion-H appears to be a very useful catalyst for transalkylation reaction as indicated in these studies. Transalkylation of benzene with diethylbenzenes, as well as with diisopropylbenzene, is efficiently catalyzed by Nafion-H in a flow system. The efficiency of the catalyst is, however, more limited when the transferring group is a methyl group.\(^{268}\) Beltrame and co-workers have also carried out\(^{269}\) detailed mechanistic studies on the isomerization of xylenes over Nafion-H.

The use of Nafion-H in de-tert-butylation—in fact, trans-tert-butylation—has been extensively studied by Olah, Yamato, and co-workers. An early study established\(^{275}\) that tert-butyl-substituted aromatics, when treated in the presence of a suitable acceptor compound, are easily de-tert-butylated over Nafion-H used in catalytic amount [Eq. (5.106)]. Additional compounds including substituted biphenyls, bibenzyls, and cyclophanes, along with a range of substituted tert-butylphenols, all gave de-tert-butylated products in high (80–97%) yields.
2-Amino- and 2-acetamino-4-tert-butyltoluene, in turn, are unreactive. In the case of 2,2',6,6'-tetramethyl-4,4'-di-tert-butyl diphenylmethane, trans-debenzylation competes with trans-tert-butylation. It was also observed in the ring closure of 2,2'-dihydroxybiphenyls\textsuperscript{276} (see Section 5.14.1.1).

![Chemical structure](image)

\( R = \text{Me, MeO} \)

\( R' = \text{H, Me} \)

\( 98\text{--}100\% \text{ yield} \)

\( \text{Me} + \text{Me} \xrightarrow{\text{Nafion-H, reflux, 2--12 h}} \text{Me} + \text{Me} \)

Subsequently, Yamato and co-workers\textsuperscript{277--280} successfully applied trans-tert-butylation in the multi-step synthesis of various polycyclic aromatic compounds, where the tert-butyl group served as a positional protective group and could be easily removed in the final step. The method was also applied to introduce the tert-butyl group into a suitable position in the aromatic ring using 2,6-di-tert-butyl-para-cresol\textsuperscript{281} [Eq. (5.107)]. The de-tert-butylation of para-tert-butylcalix[4]arene has also been reported\textsuperscript{282} and the process (with toluene under reflux or para-xylene at 120°C) was found to be more convenient than the widely employed AlCl\textsubscript{3}-catalyzed reaction. In addition, the use of Nafion-H allows the isolation of partially de-tert-butylated products.
Nafion-H is also very efficiently catalyzes the rearrangement of anisole, methylanisoles, and phenetole to ring-alkylated phenols and products of transalkylation when vapors of the alkyl aryl ethers are passed over it at temperatures higher than 160°C. 208,268 At these reaction temperatures, some of the starting alkyl phenyl ethers undergo cleavage of the alkyl group to give phenol.

Recently, the results of the isomerization and transalkylation of isomeric diethylbenzenes with benzene in the presence of triflic acid have been reported. The aim is to find the best condition for the preparation of ethylbenzene. 283–285 Ortho-diethylbenzene and benzene reacting in 1:1 molar ratio at 35°C gave ethylbenzene in 49% yield in 6 h. 285 An even higher yield was obtained with para-diethylbenzene (51% at 22°C), whereas meta-diethylbenzene produced ethylbenzene only in 29% yield. 283 Both decreasing temperature and decreasing diethylbenzene/benzene ratio resulted in decreasing yields.

5.2.7. Alkylation with Miscellaneous Reagents

In liquid-phase alkylations besides conventional Friedel–Crafts systems, superacids that are capable of forming stable carbocations and onium ions have also found applications. Olah, 128 in his extensive studies, has shown that alkyl halides readily ionize in SbF₅ to the corresponding alkylcarbenium hexafluoroantimonates. Tertiary and some secondary carbocations are remarkably stable in solutions of SO₂–SbF₅ and SO₂ClF–SbF₅, respectively. These systems were also found to be highly efficient aromatic alkylation agents (their ability to alkylate saturated aliphatic hydrocarbons was discussed in Section 5.1).

Methyl fluoride and ethyl fluoride form stable addition complexes with SbF₅, which are powerful methylating and ethylating agents, respectively. 143,144 In the study of alkyl halide–antimony pentafluoride systems, Olah and DeMember 287 found that dialkylhalonium ions R₂X⁺ are formed when 2 mol (or excess) of an alkyl halide (except fluoride) are reacted with SbF₅ (see Section 4.2.4) in SO₂ or SO₂ClF solution. The alkylation of aromatic hydrocarbons, such as benzene, toluene, and ethylbenzene, has been studied with highly electrophilic dimethylhalonium and diethylhalonium hexafluoroantimonates (72a and 72b) in SO₂ClF solution under superacidic conditions 288 [Eq. (5.108)]. Data for alkylations are summarized in Table 5.23.

All data are the average of at least three parallel experiments.
Dimethyl-chloronium and -bromonium ions give similar methylation results and are quite reactive even at temperatures as low as $-50^\circ C$. The dimethyliodonium ion is less reactive and alkylates benzene and toluene in $SO_2CIF$ solution only when allowed to react (if necessary under pressure) at or above $0^\circ C$.

The ethylation of toluene by diethylhalonium ions gives ethyltoluenes with ortho:para isomer ratios between 0.60 and 0.96. The ortho:para isomer ratios obtained for the alkylation of toluene in conventional Friedel–Crafts ethylations range from 1.17 to 1.84 (average $\sim 1.60$). Such differences are considered to be due to the steric ortho effect caused by diethylhalonium ions, and are in accordance with the most probable displacement reaction on the bulky diethylhalonium ions by the aromatic substrate. This can be envisioned to proceed through an $S_N2$-type transition state involving no free alkyl cations [Eq. (5.109)].

The alkylation data obtained from the reaction of dimethyl- and diethylhalonium ions provide evidence for direct alkylation of aromatics by dialkylhalonium ions. In addition, the data also indicate that dialkylhalonium ions are not necessarily involved as active alkylating agents in general Friedel–Crafts systems, although some of the reported anomalous alkylation results, particularly with alkyl iodides, could be attributed to reaction conditions favoring dialkylhalonium ion formation.

Vol’pin and co-workers$^{289}$ used the superelectrophilic reagent $CBr_4-nAlBr_3$ to alkylate pentafluorobenzene a deactivated arene with propane to form the isopropylated derivative in almost quantitative yield (Scheme 5.32). In the absence of propane, tribromomethylation takes place in a slow reaction. The suggested mechanism involves cation $C_6F_5^+$ formed by hydride abstraction induced by $CBr_3^+$. The formed intermediate cation then reacts with either propane or propene also formed by hydride abstraction to give the alkylated product. Pentafluorobenzene was also alkylated with perfluoroindane promoted by $SbF_5$ to yield perfluoro-1-phenylindane in 61% yield ($C_6F_6$ solvent, $22^\circ C$, 3.5 h).$^{290}$

A variety of substituted aromatics have recently been found to be effective in alkylation. Phenols, naphthols, and their ethers,$^{291,292}$ 5-amino-1-naphthol,$^{293}$ hydroxyquinolines$^{294,295}$ and hydroxyisoquinolines$^{295,296}$ [Eq. (5.110)] are activated
under superacidic conditions (HF–SbF$_5$, AlCl$_3$ or AlBr$_3$) to form intermediate dications, which serve as the alkylating agents to produce partially saturated cyclic carbonyl compounds.

Quinoline and isoquinoline react in an analogous manner with benzene in conjugated superacids (HCl–AlCl$_3$, HBr–AlBr$_3$) to yield predominantly cis-5,7-diphenyl-5,6,7,8-tetrahydroquinoline and cis-6,8-diphenyl-5,6,7,8-tetrahydroisoquinoline, respectively (75–94% yield). The regioselectivity observed corresponds to the most stable dicationic intermediates 73 and 74. Unsaturated imides exhibit similar behavior in triflic acid (Scheme 5.33).

Klumpp and co-workers have recently shown that 2-oxazolines, which are prone to ring opening, when bearing a phenyl substituent at C(5) are capable of alkylating weak nucleophiles under superacidic conditions to yield phenyl-substituted amides [Eq. (5.111)]. Benzene and even ortho-dichlorobenzene could be alkylated in excellent yield. The diprotonated ring-opened intermediate 75 has been invoked to interpret the reactions.
Protonated phenols and phenol ethers formed in superacids can be trapped by aromatics (benzene, naphthalene, tetrahydroquinoline).\textsuperscript{292,300} The products are either cyclohexenone derivatives\textsuperscript{301} [Eq. (5.112)] or aryl-substituted phenols. In the reaction of phloroglucinol with benzene, the diphenyl-substituted derivative is the main product [Eq. (5.113)], whereas 1,3,5-trimethoxybenzene gives selectively the monophenyl derivative (80\% yield). Protonated dicationic species, such as \textbf{76}, detected by Olah and Mo\textsuperscript{302} using NMR, were suggested to be intermediates in these processes.

\[ \text{OR} \]
Substituted alkynes (disubstituted propynones, 3-arylpropyonates) are used to perform alkenylation of varied benzene derivatives in the presence of HSO$_3$F and triflic acid.$^{303-305}$ It is known$^{306}$ that arylpropionic acids and esters substituted with electron-releasing groups on the aromatic ring are protonated in HSO$_3$F at C(2) to give the unstable vinyl cation 77, which, in turn, alkylates aromatic compounds to furnish isomeric alkenes in moderate yields [Eq. (5.114)].

Depending on the substitution pattern and reaction conditions, however, dimerization may take place; that is, the intermediate vinyl cation alkenylates another acetylenic molecule (self-alkenylation)$^{305,307}$ [Eq. (5.115)].

Alkynes bearing an adjacent $N$-heterocycle, such as 5-ethynyl-1-methyl-imidazole and 1-propargylbenzotriazole, readily alkylate benzene in the presence of triflic acid to yield diphenyl-substituted products.$^{308}$ Isomeric ethynylpyridines exhibit distinct differences in reactivity: 3-ethynlypyridine exhibits the highest reactivity, whereas 2-ethynlypyridine is the least reactive [Eq. (5.116)]. This is consistent with the involvement of dicationic intermediates as the de facto alkylating agents. Indeed,
calculations showed (B3LYP/6-311G** level), that of the three dications with vinyl cation moiety, 78 is the most stable formed most easily.

5.2.8. Cyclialkylation

Electrophilic ring closure of aryl-substituted compounds such as alkenes, halides, alcohols, and carbonyl compounds called cyclialkylation can be induced by conventional Friedel–Crafts catalysts and by superacids. Examples are also known in which an intermolecular alkylation step is followed by intramolecular alkylation of the intermediate to furnish a cyclic product.

A range of diols and cyclic ethers were used to carry out alkylation of aromatics (benzene, toluene, xylenes, trimethylbenzenes, naphthalene) in the presence of triflic acid.\(^{204,310}\) In a recent study,\(^{311}\) various methyl-substituted benzene derivatives were alkylated with 1,4-diols [Eq. (5.117)] to form substituted tetralin derivatives in high yields. The transformations involve an intermolecular alkylation step followed by intramolecular alkylation (cyclialkylation). \(^{2,2,5,5}\)-Tetramethyltetrahydrofurane is similarly effective. For example, it alkylates benzene to give octamethyloctahydanthracene (98% yield) and reacts with naphthalene to yield octamethyloctahydrotetracene [Eq. (5.118)].

\[\text{[51–95% yield]}\]
Török and co-workers\textsuperscript{312} have reported the one-pot synthesis of \(N\)-arylsulfonyl heterocycles through the reaction of primary aromatic sulfonamides with 2,5-dimethoxytetrahydrofuran. When triflic acid is used in catalytic amount, \(N\)-arylsulfonylpyrroles are formed (Scheme 5.34). Equimolar amount of triflic acid results in the formation of \(N\)-arylsulfonylindoles, whereas \(N\)-arylsulfonylcarbazoles are isolated in excess acid (Scheme 5.34). In the reaction sequence 1,4-butanedial formed in situ from 2,5-dimethoxytetrahydrofurane reacts with the sulfonamide to give the pyrrole derivative (Paal–Knorr synthesis). Subsequently, one of the formyl groups of 1,4-butanal alkylates the pyrrole ring followed by a second, intramolecular alkylation (cyclialkylation) step.

Intramolecular alkylation of aryl ketones with the concomitant elimination of water, also called cyclodehydration,\textsuperscript{313} has been studied by Shudo and co-workers.\textsuperscript{314} Cyclodehydration of 1,3-diphenylpropanones to give 1-phenyl-1\(H\)-indenones [Eq. (5.119)] shows strong dependence on acidity.

The reaction of the parent compound did not take place in trifluoroacetic acid (TFA), but did proceed on the addition of triflic acid to give the alkylated product in low yield (Table 5.24). In neat triflic acid the reaction is faster and the product is formed in much higher yield. Similar changes were observed with the other 1,3-diphenylpropanones. Substituents on the benzoyl group also induce significant differences in reactivities (compare the results for $R’$ = Me and CF₃ in Table 5.24). These observations suggest that the protosolvated dicationic species 79 is involved in the rate-determining step of cyclization (Scheme 5.35).

Cyclodehydration has been used to prepare the antihistamine precursor 80 under superacid conditions $^{315}$ [Eq. (5.120)].

\[ \text{80} \quad 91\% \text{ yield} \]  

The related transformation of 1-phenyl-2-propen-1-ones 81 (a Nazarov-type cyclization) [Eq. (5.121)] has also been studied by Shudo and co-workers. $^{316}$ The acidity dependence (Table 5.25) and, in particular, the linear relationship between rates and acidity values strongly suggest the involvement of $O,O$-diprotonated
intermediates. In agreement with earlier observations, an electrocyclization mechanism rather than Friedel–Crafts type reaction is suggested to be operative. According to calculations (B3LYP/6-31G*+ZPE), the energy barrier of the electrocyclization of the carbenium–oxonium dication of the parent compound through transition state 82 is much lower than that of the monocation through transition state 83 (12.4 kcal mol$^{-1}$ versus 24.9 kcal mol$^{-1}$). Appropriate substitution ($R' = \text{Me}$) lowers the energy barrier even further (9.0 kcal mol$^{-1}$). A similar study with respect to the cyclization of hydroxycarbonyl compounds 84 likewise indicated the involvement of diprotonated species 85 [Eq. (5.122)]. 3-Arylbenzofurans affording the same intermediate show the same transformation. Subsequently, the substituent effects of electrocyclization of similar systems were also studied to explore the synthetic utility of the reaction.

$^a$Acidity function values are corrected for the reaction media.
Coxon, Steel, and co-workers studied the transformations of a series of phenylalkanols in fluorosulfuric acid at low temperature to find a variety of reaction modes. Cyclization of 2-phenylethanols, in most of the cases, is accompanied by rearrangement to afford various polycyclic products. The formation of propellane \(86\) was rationalized by the plausible mechanism shown in Eq. (5.123).
3-Phenylpropanols generally undergo rearrangement prior to cyclization. For example, the reaction of 1-(2-phenylethyl)cyclohexanol (87, R = H) in HSO₃F gives a mixture of two products (88 and 89) in a ratio of 1:3 in 40% yield (Scheme 5.36). The initially formed tertiary cation yields the spiro compound 88. The 1,2-hydride shift to give the secondary cation, however, competes successfully with the first process and results in the preferential formation of the octahydrophenanthrene derivative 89. This latter cyclization is stereoselective; this affords only the less stable cis isomer, indicating that it is a kinetically controlled product. In the transformation of the 2-methyl derivative (87, R = Me), only isomeric octahydrophenanthrenes were isolated (80% yield, 90a/90b = 3:1). In this case, formation of the spiro compound is not competitive with hydride transfer to form the other tertiary carbocation. 4-Phenylbutanols undergo direct cyclization of the initially formed carbocation to give tetralin derivatives.

Sommer and co-workers have performed detailed studies of the cyclization of 1,3-diarylpropynones to form 3-arylindenones in various superacids (TiOH, TiOH–SbF₅, HF–SbF₅, HSO₃F; –H₀ = 14–20). In the superacid HSO₃F, the starting compounds with electron-withdrawing R substituents undergo protonation at the carbonyl oxygen to give stable carbocationic intermediates characterized by ¹H and ¹³C NMR spectroscopy (−80°C and 0°C). Electron-releasing R groups, in turn, increase the electron-density of the ynone moiety and the intermediates undergo ring closure to 3-arylindenones [Eq. (5.124)]. O-Protonated and C-protonated intermediates 91a and 91b and O,C-diprotonated dication 92 have been proposed to participate in product formation.
It has been reported in a follow-up study,\textsuperscript{324} that the product 3-arylindenones underwent double protonation in strong superacids (HSO\textsubscript{3}F, CF\textsubscript{3}SO\textsubscript{3}H) and the stability of formed species allowed their observation by NMR spectroscopy at room temperature. Although fast proton exchange prevented to observe $O$-protonation, $^1$H and $^{13}$C chemical shifts unequivocally showed the presence of dication 93.

Shubin and co-workers\textsuperscript{325} have generated long-lived cyclobutenyl cations and studied their varied rearrangements, which involve cyclialkylation steps. For example, cation 94 gives the isomeric pentacycle 95 under superacid conditions [Eq. (5.125)].
Further treatment of product 95 in triflic acids allows the isolation of the isomeric product via ring-opening–ring-closing reaction steps [Eq. (5.126)].

Triflic acid has been used in the ring closure of allyl-substituted heterocycles to synthesize compounds 96 and 97,\textsuperscript{326} whereas isomeric compounds 98 was isolated in the reaction of propargyl-substituted benzylamines.\textsuperscript{308}
Tricationic and dicationic intermediates were suggested to be involved in the intramolecular cyclization of 2-nitromethylene-1-phenylalkyl-substituted $N$-heterocycles with the participation of superelectorophilic hydroxynitrilium cation 99 to give tricyclic products in triflic acid\textsuperscript{327} (Scheme 5.37). Likewise, the intramolecular trapping of the intermediate hydroxynitrilium cation affords the six- to nine-membered ring oximinoorthodithiolactones\textsuperscript{328} [Eq. (5.127)].

Scheme 5.37
Construction of the 1,2,3,4-tetrahydroisoquinoline skeleton through cyclialkylation has also been achieved with triflic acid. Elevated temperature is required to transform aldimines of 2-arylethylamine (Pictet–Spengler cyclization) to substituted tetrahydroisoquinolines\textsuperscript{329} [Eq. (5.128)]. Kinetic and acidity dependence studies and substituent effects led to postulation regarding the intervention of the dicationic species 100 in the rate-determining cyclization step. In a subsequent study,\textsuperscript{330} high stereoselectivity was observed under superacidic conditions particularly for 2-alkyl-N-benzylidene derivatives as compared with the corresponding reactions in weak acid (TFA). N-Acyl enamino ketones were assumed to react with the involvement of an iminium ion intermediate to give the N-acyl tetrahydroisoquinoline derivatives in good yield\textsuperscript{331} [Eq. (5.129)].

\begin{align*}
\text{Reimann et al.}\textsuperscript{332} & \text{ have performed the stereoselective ring closing of the diastereomeric mixture of piperidinols 101 and isolated the product ergoline with a C/D cis configuration in low yield [Eq. (5.130)]}. \text{ It was also observed, however, that one of the isomers afforded the product quantitatively under identical conditions, whereas the other slowly decomposed.}

(5.130)

\(N\)-acyliminium ions, in general, are widely used in the formation of varied ring systems.\(^{333}\) Triflic acid was applied in the synthesis of polycyclic compounds 102 and 103 starting from hydroxy lactam precursors,\(^{334,335}\) whereas a lactone was transformed to compound 104.\(^{336}\)

\text{R}^2 = \text{H, Ph} & \quad \text{R}^3 = \text{Ph, 4-FC}_6\text{H}_4, \text{C}_6\text{F}_5 \\
\end{align*}
\]

37–97% yield

(5.131)
Detailed experimental and theoretical investigations were subsequently performed with 1-methyl-5-hydroxypyrrolidin-2-one. It was shown that *para*-dimethoxybenzene, a stronger nucleophile, is able to react in CF₃COOH, whereas the deactivated aromatic *para*-dichlorobenzene is unreactive. However, it gives the alkylated product in 67% yield in the presence of excess triflic acid. These observations show that ion 105 formed in CF₃COOH can react with the activated aromatic, but further protolytic activation—that is, formation of protosolvated species 106a or dication 106b—is required to induce the transformation of the deactivated compound. Cation 105 was identified by ¹H and ¹³C NMR spectroscopy under stable ion conditions (HSO₃F–SO₂ClF). In the even stronger acid HSO₃F–SbF₅ at −40°C, two sets of peaks appeared with all ¹H NMR resonances significantly deshielded. Notable is the chemical shift of the iminium proton at δ¹H 9.42. The carboxonium and iminium carbon signals of the fully protonated dication 106b in the calculated gas-phase NMR spectrum are significantly deshielded from those in the experimental spectrum suggesting the formation of the protosolvated structure 106a.

Acylium salts undergo aza-Nazarov cyclization under similar conditions to form varied five-membered *N*-heterocycles. Aryl-tethered pyrrolinones and dihydro-pyridones [Eq. (5.132)] were induced to cyclize with triflic acid to afford tri- and tetracyclic products.
When 5- and 8-hydroxyquinolines and 5-hydroxyisoquinoline are used as alkylating agents (see Section 5.2.7) the primary alkylation products undergo a second, intramolecular alkylation to form methano-bridged compounds in low yields, which is due to the reversibility of the reactions\textsuperscript{294,295} [Eq. (5.133)].

\begin{equation}
\text{NHBr}^{-} + \text{AlBr}_{3} \xrightarrow{\text{reflux, } 20\, \text{h}} 54\% \text{ yield}
\end{equation}

(5.133)

The alkylation method developed by Fukuzawa et al.\textsuperscript{245} (see Section 5.2.4) has been used in cyclialkylation to synthesize polycyclic aromatic hydrocarbons such as benzopentaphene \textsuperscript{107} [Eq. (5.134)].\textsuperscript{341}

\begin{equation}
\text{CHO} + \text{CHO} + \text{CF}_{3}\text{SO}_{3}\text{H} \xrightarrow{\text{solvent, reflux}} \text{107}
\end{equation}

(5.134)

Nafion-H has been shown to promote cyclialkylation of arylalkylepoxides to form tetrailin derivatives\textsuperscript{342} [Eq. (5.135)]. The reactions were performed by passing a solution of the epoxide in a solvent mixture (\text{CH}_{2}\text{Cl}_{2}, \text{CFCl}_{3}, 1,1,2,2-tetrafluoroethanol) through a 0.8-cm × 10-cm column packed with Nafion powder. Aryl-alkenes and -alkanols could also be used as starting materials.\textsuperscript{343}

\begin{equation}
\text{R} = \text{H, Me, MeO, F, Cl} \quad \text{R'} = \text{H, Me, MeO}
\end{equation}

(5.135)
Doyle et al.\textsuperscript{344} and Wee and Liu\textsuperscript{345} have reported the ring-closing transformation of \(\alpha\)-diazooacetamides \textsuperscript{108} and \textsuperscript{109} to yield \(2(3H)\)-indolinones over Nafion-H [Eq. (5.136)]. In the transformation of compounds \textsuperscript{109} the electrophilic intramolecular substitution is followed by decarboxylation.\textsuperscript{345} Small amounts of 2-azetidinone derivatives (4–10\%) formed through a carbene intermediate were also detected. The yield of products from compounds \textsuperscript{108} are even higher than observed in the presence of \(\text{Rh(OAc)}_2\) often applied in the decomposition of diazo compounds.\textsuperscript{344}

\[
\begin{align*}
\text{Nafion-H} & \text{CHCl}_3, \text{reflux, overnight} \quad \text{Nafion-H} \\
\text{toluene, reflux, 20 h} & \\
\end{align*}
\]

\textbf{5.3. ACYLATION OF AROMATICS}

Friedel–Crafts acylation of aromatics is of considerable practical value owing to the importance of aryl ketones and aldehydes as chemical intermediates.\textsuperscript{346} Whereas alkylation of aromatics with alkyl halides requires only catalytic amounts of catalysts, acylation to ketones generally necessitates equimolar or even some excess of the Friedel–Crafts catalysts. Usually one molar equivalent of catalyst combines with an acyl halide, giving a 1:1 addition compound, which then acts as the active acylating agent [Eq. (5.137)].

\[
\begin{align*}
\text{RCOX} + \text{AlX}_3 & \rightarrow \text{RCOX} \text{AlX}_3^{-} \\
\text{RCO}^+ \text{AlX}_4^- & \\
\end{align*}
\]

Evidence supporting the formation of 1:1 addition compounds is further substantiated by the actual isolation of stable acyl cation salts (Chapter 3). Therefore, it is highly desirable to develop methods in which only a catalytic amount of Friedel–Crafts acid catalyst may be used for effective conversion.

Effenberger and Epple\textsuperscript{347} showed that alkylbenzenes are effectively acylated when \(~1\%\) triflic acid is added to the mixture [Eq. (5.138)] (Table 5.26). It was shown that when other Brønsted or Lewis acids were used, the yield decreased drastically (Table 5.27). Perfluorobutanesulfonic acid was found similarly effective (35–84\% yields)\textsuperscript{348} [Eq. (5.138)].
Acyl chlorides were also tested in acylations promoted by B(OTf)_3. 231 Acylation of benzene and toluene in competitive reactions (molar ratio = 5:1) with acetyl chloride shows high para selectivity (92–95% with 2.5–7% of meta, k_T/k_B = 31–73), whereas the para isomer is formed only with 72–75% selectivity (8–10% of meta, k_T/k_B = 78) in benzoylation with benzoyl chloride. Acetylation appears not to be affected by significant isomerization as indicated by isomer distributions and relative reactivity data.

</table>
Triflic acid has been found to be an effective catalyst in the aroylation of fluorobenzene with 3- and 4-trifluoromethyl- and 3,5-bis(trifluoromethyl)benzoyl chloride.\(^{349}\) Although a prolonged treatment is required (reflux, 144 h), the reactions proceed with high selectivity to give the desired CF\(_3\)-sustituted 4-fluorobenzophenones in high yields (79–98%).

Studies on mixed anhydrides of carboxylic acids and triflic acid have shown them to be extremely powerful acylating agents.\(^{350}\) Similarly, higher perfluoroalkanesulfonic acids also form mixed anhydrides.\(^{351}\)

Triflic acid has been shown to exhibit high activity in the acylation of aromatics with methyl benzoate to give benzophenone derivatives in good to excellent yields\(^ {352}\) [Eq. (5.139)]. Aromatic carboxamides bearing an additional functional group, when protonated by triflic acid to form activated dicationic intermediates, are capable of reacting with benzene to yield acylated products.\(^ {253}\) Triflic acid also activates \(\beta\)-lactams to react with arenes to form aryl-substituted \(\beta\)-amino ketones\(^ {353}\) [Eq. (5.140)]. Naphthalene, ferrocene, and \(N\)-substituted pyrroles were also reacted. In all three reactions, diprotonated cationic intermediates were invoked for interpretation of the results.

\end{align*}
\]

Roberts and Wells\(^ {354}\) were the first to use triflic acid in the acylation of phospaferrocenes with acetic anhydride and benzoic anhydride to afford ketophosphaferrocenes in good yields (62–78\%). Recently, acyl trifluoroacetates in excess triflic acid have been shown to be even more effective reagents\(^ {355}\) [Eq. (5.141)].
Amorphous and mesostructured ZrO₂ solid catalysts impregnated with various amounts of triflic acid were tested in the acylation of biphenyl and toluene (with benzoyl chloride and para-toluyl chloride, respectively, nitrobenzene solvent, 170°C and 130°C). All catalysts exhibited lower activity when compared with neat triflic acid. The mesoporous catalysts, however, showed complete selectivity in the formation of para-benzoylbiphenyl. A triflic acid–silica catalyst, in turn, prepared using an aminopropyl-modified silica, showed good characteristics in the solvent-less acetylation of anisole and 2-methoxynaphthalene with acetic anhydride. The activity of 1,1,2,2-tetrafluoroethanesulfonic acid, either neat or embedded in silica, was found to be similar to that of triflic acid in the acetylation of anisole.

The protonation of a series of α-substituted cinnamic acid in HSO₃F at −78°C has been studied. The protonated (Z)-α-phenyl cinnamic acid intermediate undergoes further transformation to yield 2-phenylindenone as a result of intramolecular acylation [Eq. (5.142)].

Klumpp and co-workers have performed a detailed study of the acylation reactions of benzene with a variety of cinnamic acid derivatives in triflic acid. Cinnamic acids with alkyl or weakly electron-withdrawing groups (F, Br) on the phenyl ring give the corresponding substituted indanones as a result of a two-step
intermolecular and intramolecular acylation (61–98% yield). In addition to indanone derivatives, dihalogenated cinnamic acid derivatives yield chalcones the products of intermolecular acylation of benzene [Eq. (5.143)]. Note that the unsubstituted (i.e., more electron-rich) ring participates in the ring closure. Finally, only chalcones are formed with compounds with strong electron-withdrawing groups. In a large excess of triflic acid (100 equiv.) triarylpropanones are also detected. The suggested mechanism involves diprotonated cationic intermediates with the reactivity of the cationic center greatly enhanced by the adjacent protonated carboxylic or carbonyl group (Scheme 5.38).

The intramolecular acylation of 2-aryloxybenzonitriles allowed the synthesis of molecules with dixanthone skeleton. The procedure, in fact, is an intramolecular Houben–Hoesch reaction to afford the intermediate bisiminium salts [Eq. (5.144)] which, after hydrolysis, gave the final diketo products.
Examples of a two-step process of intermolecular alkylation followed by intramolecular acylation have also been reported. 5-Aryltetrahydrofuran-2-ones undergoing ring opening in triflic acid to give the intermediate benzyl cation, which alkylates benzene or chlorobenzene followed by intramolecular acylation to afford tetralone derivatives in low yields \(^\text{[Eq. (5.145)]}\). The reaction of aromatics with \(\alpha,\beta\)-unsaturated carboxylic acids in triflic acid is a general method to synthesize substituted indanones \(^\text{[Eq. (5.146)]}\). The alkylation–acylation sequence was deduced from the observations that in certain reactions (benzene with crotonic acid and phenol with styrylacetic acid), only acylated products are formed. Likewise, 1-tetralones are produced from \(\beta,\gamma\)-unsaturated carboxylic acids.
Nafion-H has also been found to be an effective catalyst for heterogeneous acylation of aromatic hydrocarbons with aroyl chlorides and anhydrides.\textsuperscript{367}

The reported gas-phase acylations with Nafion-H catalyst were generally carried out at the boiling point of the hydrocarbon to be acylated. The yield of aroylation reaction depends on the relative amount of the catalyst used. Optimum yields were obtained when 10–30\% of Nafion-H was employed relative to the aroyl halide. Although this procedure allows very clean reactions with no complex formation and easy work-up procedures, it is presently limited to only aroylation. Attempted acetylation of aromatics with acetyl chloride under similar conditions led to thermal HCl elimination from the latter to form ketene and products thereof. In the reaction of acetyl chloride by itself with Nafion-H, diketene was detected by IR and NMR spectroscopy.\textsuperscript{367}

Olah, Prakash, and co-workers\textsuperscript{368} have shown that direct aroylation with arene-carboxylic acids including pentafluorobenzoic acid can be performed over Nafion-H. Arenes, with the exception of benzene and toluene, react in the liquid phase at reflux temperature to give benzophenone derivatives in moderate to good yields [Eq. (5.147)]. Intramolecular Friedel–Crafts acylations can be performed under similar conditions by the reaction of arylalkyl-benzoic acids or arylalkyl-benzoic acids in \textit{para}-xylene,\textsuperscript{369} or treating benzoic acids bearing an \textit{ortho} substituent with a phenyl group in dichlorobenzene\textsuperscript{370} [Eq. (5.148)].

Nafion–silica nanocomposite catalysts have also been tested in the Friedel–Crafts acylation of aromatics with acyl chlorides.\textsuperscript{191,194,371} Anisole, toluene, and
xylenes, when reacted with phenylacetyl and phenylpropionyl chloride, give the corresponding ketones with high selectivity.\textsuperscript{371} Hybrid organic–inorganic silica catalysts modified with superacidic fluoroalkanesulfonic acid groups (catalysts 48 and 49, Figure 5.15) showed high specific activity exceeding that of Nafion NR50.\textsuperscript{192} The rapid formation of the ortho isomer was observed in the benzylation of anisole, followed by a slower isomerization to the para isomer.\textsuperscript{372} This process, however, was shown to be not an isomerization reaction, but a transacylation occurring between anisole and ortho-benzoyl anisole. Furthermore, a catalyst with a more hydrophobic character led to more complete isomerization (para/ortho = 62.5). Nafion SAC-13, in turn, gave the acylated product in low yield (10\%) when para-xylene was reacted with heptanoic acid. Among the byproducts, dimeric para-xylene was identified.\textsuperscript{373}

Acetic anhydride was found to be very effective in the acetylation of anisole over silica with anchored perfluorinated sulfonic acid site 48 (Figure 5.15).\textsuperscript{374} Activity of catalysts with high surface concentration of sulfonic acid groups exceeded that of Nafion SAC-13. Rapid deactivation, however, was observed at elevated temperature. A study of Nafion SAC-13 applied in continuous operation\textsuperscript{375} (anisole:acetic anhydride molar ratio of 5, 70°C) arrived at the same conclusion: para-methoxyacetophenone was formed with high selectivity (>95\%), but the initial activity (40–50\% conversion) was completely lost in 24 h. Treatment of the spent catalyst with boiling HNO\textsubscript{3} (40\% solution), however, successfully restored the activity by removing strongly adsorbed acylated products. Acylation of anisole with octanoic acid was also studied.\textsuperscript{376,377} Nafion SAC-25 with mesopores larger than those of SAC-13—and, consequently, more accessible nanoparticles—show the highest specific activities (Table 5.28). Because of competitive adsorption, removal of water formed is essential for optimal catalyst performance.

The reversibility of Friedel–Crafts acylation is only occasionally observed.\textsuperscript{378–383} Schlosberg and Woodbury\textsuperscript{384} have studied transacylation between tetramethylacetophenones and some arenes in superacidic HF–SbF\textsubscript{5} (5:1) and other strong superacid media. In fact, Keumi and co-workers\textsuperscript{385} have been able to observe diprotonated acetylpentamethylbenzene intermediate \textit{111} in HSO\textsubscript{3}F–SbF\textsubscript{5}–SO\textsubscript{2}Cl\textsubscript{2} medium at low temperatures, which deacetylates to pentamethylbenzenium ion at more elevated temperatures [Eq. (5.149)].

Reaction conditions: anisole/acid molar ratio = 40, 0.3 g of catalyst, 150°C. 

$^a$Selectivity of the para isomer at 50\% conversion.
Sarca and Laali\textsuperscript{386} have developed a convenient process for transacylation of sterically crowded arenes such as acetylmesitylene [Eq. (5.150)] and tetramethyl- and pentamethylacetophenones to activated aromatics using triflic acid in the presence of imidazolium-type ionic liquids under mild conditions. When the reactions are run without an activated arene acceptor, efficient deacylation takes place. Simple 4-methoxyaryl methyl ketones can be transacetylated with toluene and para-xylene as acceptors with triflic acid.\textsuperscript{387} Nafion-H has been found to be an efficient catalyst for the decarboxylation of aromatic carboxylic acids as well as deacetylation of aromatic ketones.\textsuperscript{388}

Apparently, only a single example is known for deformylation of aromatics reported by Yamato et al.\textsuperscript{389} Treatment of 9-formylanthracene derivatives in the presence of a large excess (200 wt\%) of Nafion-H resulted in the formation of the deformylated product (Scheme 5.39). For the di-\textit{tert}-butyl-substituted derivative, selective deformylation and concomitant de-\textit{tert}-butylation could be achieved under appropriately selected reaction conditions.

Akhrem et al.\textsuperscript{390} have reported a unique method for the acylation of aromatics. When alkanes and cycloalkanes (propane, butane, cyclopentane, cyclohexane) are treated with C\textsubscript{Br}\textsubscript{4}-2AlBr\textsubscript{3} in the presence of carbon monoxide, the intermediate acyl cations react with aromatic silanes to yield acylated products by desilylative acylation [Eq. (5.151)]. The \textit{ipso}-substitution of trimethylsilane takes place regioselectively,
except for meta-trimethylsilylanisole, which gives the para-acylated product. This was explained by suggesting the initial coordination of the acyl cation to the methoxy group and the resulting steric hindrance for the ipso attack. As a result, direct acylation at the para position occurs. Consistent with this is the observation that para-trimethylsilylanisole was unreactive even in a tenfold excess of the acyl cation. Furthermore, both toluene and anisole could be directly acylated with cyclopentane under identical conditions (92% and 81% yield, respectively).

\end{align*}
\]

The one-step double functionalization of aromatics—that is, alkylation and acylation—can be accomplished with alkanes or cycloalkanes (in large excess) using the aprotic organic superacids \(\text{RCO}^+\text{Al}_2\text{X}_7^-\) \((R = \text{alkyl, aryl}, \ X = \text{Cl, Br})^{30}\) [Eq. (5.152)]. However, the method can be used only for benzene and bromobenzene.
Activated arenes (toluene, meta-xylene, naphthalene) undergo acylation, whereas strongly deactivated arenes (nitrobenzene, acetophenone) do not react. On the basis of this information, the transformation was suggested to start with alkylation followed by the acylation step.

Fries rearrangement—that is, the transformation of phenolic esters to isomeric hydroxyphenyl ketones—is related to Friedel–Crafts acylations.\textsuperscript{392,393} Olah et al.\textsuperscript{394} have found a convenient way to perform the Fries rearrangement of a variety of substituted phenolic esters in the presence of Nafion-H in nitrobenzene as solvent [Eq. (5.153)]. A catalytic amount of Nafion-H is satisfactory, and the catalyst can be recycled. In contrast, Nafion–silica nanocomposites, in general, exhibit low activities in the Fries rearrangement of phenyl acetate to yield isomeric hydroxyacetophenones.\textsuperscript{239,395} In a recent study, BF\textsubscript{3}–H\textsubscript{2}O was found to be highly efficient under mild conditions (80°C, 1 h) to transform phenolic esters of aliphatic and aromatic carboxylic acids to ketones (71–99% yields).\textsuperscript{396} In most cases the para-hydroxyphenyl isomers are formed with high (up to 94%) selectivity.

### 5.4. CARBOXYLATION

The Koch–Haaf reaction\textsuperscript{397} for the preparation of carboxylic acids from alkenes uses formic acid or carbon monoxide in strongly acidic solutions. The reaction between carbocations and carbon monoxide affording oxo-carbenium ions (acyl cations) is a
key step in the Koch–Haaf reaction and the topic has been reviewed by Hogeveen.\textsuperscript{398} The original studies used sulfuric acid. Subsequently, the application of liquid superacids in the Koch–Haaf carboxylation met with remarkable success. Triflic acid has been found to be by far superior to 95\% H\textsubscript{2}SO\textsubscript{4} for carboxylation of alkenes, alcohols, and esters with carbon monoxide at atmospheric pressure. This is attributed to the high acidity of triflic acid and also the higher solubility of CO in this medium as compared with H\textsubscript{2}SO\textsubscript{4}. Moreover, triflic acid has the advantage that, unlike H\textsubscript{2}SO\textsubscript{4}, it does not form electrophilic substitution products with aromatics and can be regenerated.\textsuperscript{399}

Whereas the C\textsubscript{2}–C\textsubscript{4} alcohols are not carboxylated under the usual Koch–Haaf conditions, carboxylation can be achieved in the HF–SbF\textsubscript{5} superacid system under extremely mild conditions.\textsuperscript{400} Moreover, Olah and co-workers\textsuperscript{401} have shown that even methyl alcohol and dimethyl ether can be carboxylated with the superacidic HF–BF\textsubscript{3} system to form methyl acetate and acetic acid. In the carboxylation of methyl alcohol the quantity of acetic acid increased at the expense of methyl acetate with increase in reaction time and temperature. The quantity of the byproduct dimethyl ether, in turn, decreased. Dimethyl ether gave the desired products in about 90\% yield at 250°C (90\% conversion, catalyst/substrate ratio = 1:1, 6 h). On the basis of experimental observations, first methyl alcohol is dehydrated to dimethyl ether. Protonated dimethyl ether then reacts with CO to yield methyl acetate [Eq. (5.154)]. The most probable pathway suggested to explain the formation of acetic acid involves the intermediate formation of acetic anhydride through acid-catalyzed ester cleavage without the intervention of CO followed by cleavage with HF [Eq. (5.155)].

\begin{equation}
2 \text{MeOH} + \text{HF-BF}_3 \rightarrow \text{Me}_2\text{O} + \text{Me}_2\text{OH} + \text{CO} \rightarrow \text{MeCO}^+ + \text{MeOH} \rightarrow \text{MeCOOMe}
\end{equation}

\begin{equation}
\text{MeCOOMe} \rightarrow \text{MeCO}^+ + \text{MeOH} \rightarrow \text{MeCOOMe} \rightarrow \text{MeCOOH} + \text{MeCOF}
\end{equation}

Nafion-H has also been found to be a suitable catalyst to carry out Koch-type carbonylation of a variety primary, secondary, and tertiary alcohols.\textsuperscript{402} Under optimal conditions, tertiary carboxylic acids are formed in moderate-to-good yields (Table 5.29). Increased CO pressure was shown to increase acid yields by enhancing the carbonylation of the intermediate tertiary carbocation prior to dimerization and oligomerization. Solvents had a small effect on catalyst performance, which is in contrast to the findings of Lange.\textsuperscript{403} Over Nafion NR50, acid yields of 39\% and 42\%
in heptanoic acid and pivalic acid, respectively, were reported in the carbonylation of 2,6-dimethyl-1-heptanol (150°C, 80 bar CO, 5 h), whereas only 1% of acid was formed in dodecane (99% conversion, 17.5 h).

Olah and Bukala have developed a method for the oxidative carboxylation of methyl halides with CO and copper oxides or Cu and oxygen over SbF₅–graphite [Eq. (5.156)]. Time-dependence studies indicated that the three products—methyl acetate, dimethyl ether, and methyl fluoride—were formed in parallel reactions. The reactivity of methyl halides shows the decreasing order MeBr > MeCl > MeF.

\[
\text{MeBr} + \text{CO} \xrightarrow{\text{SbF}_5-\text{graphite} \at 270^\circ C} \text{MeCOOMe} + \text{Me}_2\text{O} + \text{MeF}
\]

\end{array}
\]

Using HF–SbF₅, Yoneda et al. have obtained dicarboxylic acids from diols by reaction with CO under mild conditions. Some cyclization products were also obtained. Scheme 5.40 was suggested for the reaction.

The formation of C₆ and C₇ acids along with some ketones was reported in the reaction of isopentane, along with methylcyclopentane and cyclohexane with CO in HF–SbF₅ at ambient temperatures and atmospheric pressure. Yoneda et al. have also found that other alkanes can be carboxylated as well with CO in HF–SbF₅. Tertiary carbenium ions, which are produced by protolysis of C–H bonds of branched alkanes in HF–SbF₅, undergo skeletal isomerization and disproportionation before reacting with CO. Formation of the tertiary carboxylic acids in the

Reaction conditions: 2 g of Nafion-H, 20 mmol of alcohol, hexane, 160°C, 9 MPa CO, 22 h. <sup>a</sup>CHCl₃ as solvent.
superacid HSOF–SbF$_5$ was shown to be accelerated by the addition of Cu$_2$O to the reaction mixture.\textsuperscript{408} It was also found that alkyl methyl ketones react with CO in the HF–SbF$_5$ superacid system to form oxocarboxylic acids after hydrolysis (Scheme 5.41). Alkyl methyl ketones with a short alkyl chain (less than C$_4$) do not react under these conditions due to the proximity of the positive charge on the protonated ketone and the developing carbenium ion.\textsuperscript{409}

Sommer and co-workers\textsuperscript{410,411} have made detailed studies of the carbonylation of lower alkanes in superacidic media. Carbonylation of propane was carried out by bubbling mixtures of propane and CO through a HF–SbF$_5$ solution (molar ratio = 4:1) at –10°C and monitoring the composition of the solution by $^1$H NMR spectroscopy.\textsuperscript{412} Two acylium (acyloxonium) ions, propanoyl cation (ethylcarboxonium ion, 112) and isobutyryl cation (isopropylcarboxonium ion, 113), were detected which, upon quenching (ethanol or NaHCO$_3$/H$_2$O), give the corresponding acids or esters [Eq. (5.157)]. The two products were formed in a ratio of 2:3 using a CO/propane mixture of 3 with a propane conversion of 4%. The gas phase was shown to contain a large excess of methane (H$_2$/methane/ethane 4:89:7). In a large-scale test the ratio of the two acids were 1:6 (propane conversion = 94%). All experiments with excess CO showed the predominant formation of the ethylcarboxonium ion (112); that is, preferential C–C bond cleavage takes place.
Considering all possibilities, the protolytic cleavage of propane can be summarized according to Scheme 5.42. Since the butyryl cation was not detected, path a (involvement of n-propyl cation 34) can be excluded. Pathway b (protonation of the secondary C–H bond) is kinetically disfavored compared with protonation of the more electron-rich C–C bond (pathways c and d). The large amount of methane leaves only path c as the major activation route of propane leading to the formation of ethylcarboxonium ion 112 (formation of the ethyl cation followed by carbonylation with CO).

It was also found that the ratio of the two esters is highly dependent on the propane/CO ratio. In contrast to the preferential C–C bond cleavage and formation of ethylcarboxonium ion (112) observed at high CO/propane ratios, increasing amounts of propane result in increasing selectivities of the formation of the isopropylcarboxonium ion 113 (Figure 5.16). Under such conditions, formation of the isopropyl cation
via route \( b \) (Scheme 5.42, direct protolysis of the secondary C–H bond) can be neglected in comparison with the activation of propane by the ethyl cation. That is, the isopropyl cation is formed by the hydride transfer between the ethyl cation and propane (Scheme 5.43).

Addition of small amounts of bromine to the reaction mixture before adding the propane/CO mixture resulted in both an increase in conversion and increasing selectivity of the isopropylcarboxonium ion independently of the propane/CO ratio.\(^{413,414}\) This was accounted for by the involvement of the bromocarbonyl cation \( \text{BrCO}^+ \), which, upon protosolvation, acts as a superelectrophile exhibiting high 

![Scheme 5.42](image)

**Figure 5.16.** Selectivity of the formation of the isopropylcarboxonium (113) ion as a function of the propane/CO ratio (selectivity: \([113]/(113 + 112)\)).\(^{412}\)
reactivity toward propane. Furthermore, exclusive formation of the isopropylcarboxonium ion (113) was observed when carbonylation was performed in the presence of carbon tetrachloride or chloroform.\textsuperscript{415} This was explained by the regioselective C–H bond activation by the halomethyl cations CCl$_3^+$ and HCCl$_2^+$. Carbonylation of isobutane in HF–SbF$_5$ selectively and almost stoichiometrically occurs through the protolytic cleavage of the tertiary C–H bond to form the tert-butyl cation and subsequently pivaloic ester in high yield.\textsuperscript{410}

In a subsequent study, Sommer et al.\textsuperscript{416} have carried out the carbonylation of methylcyclopentane under two reaction conditions. When CO is bubbled through the HF–SbF$_5$ solution at −40°C, the methylcyclopentyl cation (23) yields quantitatively the corresponding carboxonium ion and, upon quenching with ethanol, gives ethyl 1-methylcyclopentane carboxylate (80% yield based on SbF$_5$) (Scheme 5.44). Carbonylation at 0°C, in turn, leads to the formation of ethyl cyclohexanecarboxylate (60% yield). Under such conditions, where carbonylation is a reversible process, the cyclohexyl carbenium ion (22), which is in equilibrium with the more stable methylcyclopentyl cation 23, has a much higher reactivity toward CO. As a result, the reaction mixture becomes enriched in the cyclohexyl carboxonium ion, the quenching of which gives the corresponding ester (Scheme 5.44).

Akhrem and co-workers\textsuperscript{417} have successfully applied aprotic organic superacids in the carbonylation of a series of alkanes. Butane was transformed into isomeric carboxylic acids depending on the superelectrophilic reagent and isolated as the
esters 114a and 114b (Scheme 5.45), whereas pentane gave 2,2-dimethylbutanoic acid selectively in almost quantitative yield in the presence of CBr$_4$–2AlBr$_3$.

Isopropyl esters of cyclohexanecarboxylic acids have been synthesized by using CBr$_4$–2AlBr$_3$ (1 atm CO pressure, $-20^\circ$C, 0.5 h). Isopropyl 1-methylcyclohexanecarboxylate was isolated in the reaction of cycloheptane and methylcyclohexane (82% and 73% yield, respectively), whereas isopropyl 1-ethylcyclohexanecarboxylate was formed from cyclooctane and ethylcyclohexane (67% and 69% yield, respectively).

It has been demonstrated by Olah et al. that $\alpha,\beta$-unsaturated ketones are O-protonated in HF–SbF$_5$ to form hydroxyallylic cations, which were directly observed by NMR spectroscopy. Jacquesy and Coustard have found indirect evidence for diprotonation of $\alpha,\beta$-unsaturated ketones (enones) by trapping the dication with CO. The resulting acylium ion centers are then quenched with methanol or benzene. An interesting synthetic method was therefore developed for carboxylation of bicyclic enones in superacid media at atmospheric pressure [Eqs. (5.158) and (5.159)].
When cyclohexene is mixed with anhydrous triflic acid under a high pressure of carbon monoxide (120 atm) followed by the addition of benzene, cyclohexyl phenyl ketone and the isomeric cyclohexenyl cyclohexyl ketones are obtained with little isomerization of the initially formed cyclohexyl cation \(22\) to methylcyclopentyl cation \(23\) (Scheme 5.46).\(^{422}\)

\[
\begin{align*}
\text{Scheme 5.46}
\end{align*}
\]

Lee et al.\(^{423}\) have reported the carbonylation of formaldehyde over various ion-exchange resins. Nafion NR50 showed the highest specific activity (moles of formaldehyde converted per proton site) yielding methyl glycolate with high selectivity [Eq. (5.160)].

\[
\begin{align*}

\]

Oxidative carbonylation of alkynyltungsten(II) complexes in excess triflic acid leads to formation of indanone derivatives\(^{424}\) [Eq. (5.161)]. Elucidation of the reaction mechanism was made by isolation and characterization of acyltungsten(IV) species indicating the involvement of the \(\eta^1\)-vinylidene cation \(115\).
Carboxylation of aromatics with carbon dioxide with Al\textsubscript{2}Cl\textsubscript{6}/Al has been studied by Olah, Prakash, and co-workers\textsuperscript{425} and shown to be a chemoselective process to give aromatic carboxylic acids in good to excellent yields (20–80°C, CO pressure = 57 atm). Two possible mechanistic pathways with the involvement of organoaluminium intermediates and complexes of CO\textsubscript{2} with AlCl\textsubscript{3} were postulated. On the basis of extensive experimental studies and theoretical calculations, the authors concluded that the most feasible mechanism involves CO\textsubscript{2} activated with superelectrophilic aluminum chloride. Complex 116 reacts with aromatics in a typical electrophilic substitution.

5.5. FORMYLATION

Aromatic formylation reactions are known to occur under Gattermann–Koch conditions using mixtures of CO + HCl + AlCl\textsubscript{3} and CuCl\textsubscript{2}.\textsuperscript{426–428} The use of superacidic HF–BF\textsubscript{3} and HF–SbF\textsubscript{5} as catalysts for aromatic formylation has been demonstrated.\textsuperscript{429–431} Mechanistic studies by Olah et al.\textsuperscript{432} have shown that selectivity in formylation reactions strongly depends on the nature of the formylating agent.

Among the most frequently used formylation methods, the Gattermann–Koch reaction shows the highest selectivity reflected both in the observed high $k_{\text{toluene}}/k_{\text{benzene}}$ rate ratios as well as a high degree of para substitution (Table 5.30).
Gross formylation with dichloromethyl methyl ether is somewhat less selective, as is the Gattermann synthesis using Zn(CN)\(_2\) and AlCl\(_3\). Friedel–Crafts-type formylation with formyl fluoride gives a much lower selectivity indicating that the HCOF–BF\(_3\) system produces a more reactive electrophile (HCOF/C\(_1\)BF\(_3\) complex, but not necessarily a free formyl cation, HCO\(^+\)).

The lowest selectivity was observed in the case of HF–SbF\(_5\)-catalyzed formylation with CO in SO\(_2\)ClF solution at \(95^\circ\)C, which gave a very low \(k_{\text{toluene}}:k_{\text{benzene}}\) ratio (Table 5.30) and an isomer distribution of 45% ortho-, 2.7% meta-, and 52.1% para-tolualdehydes. Under the superacidic conditions studied, CO is protonated to give rapidly equilibrating (with the solvent acid system) protosolvated formyl cation, an obviously very reactive electrophilic reagent. When the reaction is carried out at 0°C using only excess aromatics as solvent, the selectivity becomes higher and giving an isomer distribution of 7.5% ortho-, 2.8% meta-, and 89.8% para-tolualdehydes.

Subsequently, Olah et al. made a detailed study of the formylation of a variety of arenes (benzene, toluene, ethylbenzene, xylenes, mesitylene) in the superacidic catalyst systems triflic acid–HF–BF\(_3\) and triflic acid–SbF\(_5\). Increasing acidity was found to result in increasing yields of aromatic aldehydes. Good to high yields of aldehydes (59–78%), in general, could be achieved under mild conditions (atmospheric CO pressure, room temperature). Toluene gave isomeric ditolylmethanes through the reaction of intermediate protonated para-tolualdehyde with excess toluene. High positional selectivity (91–94% para isomer) was observed in both catalyst systems studied. Substrate selectivities (\(k_T/k_B\)), in turn, were lower (21 in triflic acid–HF–BF\(_3\) and 15 in triflic acid–SbF\(_5\)) as compared to those in Gattermann–Koch reaction. The elusive formyl cation could not be observed (triflic acid–SbF\(_5\)–SO\(_2\)ClF solution, \(-80^\circ\)C) only exchanging \(^{13}\)CO could be detected suggesting the existence of a rapidly equilibrating protosolvated ion.

The formylation of hexadeuteriobenzene, C\(_6\)D\(_6\), with HCOF–BF\(_3\) shows a kinetic hydrogen isotope effect of \(k_H/k_D = 2.68\), based on comparison of the reactivity of C\(_6\)H\(_6\)/CH\(_3\)C\(_6\)H\(_5\) and C\(_6\)D\(_6\)/CH\(_3\)C\(_6\)H\(_5\). This isotope effect is similar to that observed in Friedel–Crafts acetylation and propanoylation reactions, and it indicates that the proton elimination step is at least partially rate-determining. The low substrate

selectivity formylation with the CO–HF–SbF$_5$ system, however, shows no primary isotope effect.

Tanaka et al.\textsuperscript{436} have studied the formylation of alkylbenzenes, halobenzenes, indane, and tetralin in HSO$_3$F–SbF$_5$ under atmospheric CO pressure and observed both formylation and sulfonation. Time-dependence studies with meta-xylene showed that the formylation product is formed first and then transformed into the sulfonated aldehyde with increasing reaction time. However, selectivity could be controlled by changing the acid strength of the system, and formylated products could be obtained in high yields with high para selectivity under appropriately selected reaction conditions (high acidity, short reaction time). On the basis of additional studies by comparing formylation and sulfonation, it was concluded\textsuperscript{437} that the formyl cation has dual reactivity and can act as an electrophile or Brønsted acid. On the other hand, protonated aromatics can also act as Brønsted acids to produce formyl cations. Under typical electrophilic conditions, where most of the arenes are protonated, formyl cations are produced close to the aromatic ring by the protonated aromatics. Formylation, consequently, has priority over sulfonation.

The HF–SbF$_5$ system could be used for the synthesis of dialdehydes of bicyclic aromatic compounds.\textsuperscript{438,439} With an SbF$_5$/arene ratio of 2, naphthalene, biphenyl, diphenylmethane, and bibenzyl gave dialdehydes with high positional selectivity (31–98% yield). It was surprising to find in this study, however, that methylnaphthalenes react slowly and exhibit low positional selectivity. Subsequently, the kinetics and regioselectivity of the formylation of 1-methylnaphthalene and meta-xylene in the HF–SbF$_5$ and CF$_3$SO$_3$H–SbF$_5$ acid systems were studied.\textsuperscript{440–442} Dependence of the rate on the SbF$_5$/arene ratio revealed that formylation can be explained by taking into account the protonation equilibrium of meta-xylene and the apparent formylation rate decreasing by protonation. The extent of inhibition by protonation is related to the extent of the transformation of the arene to an inactive $\sigma$-complex. The apparent formylation rate of arenes, consequently, is not generally proportional to their relative basicities. Furthermore, high para selectivity of the formylation of 1-methylnaphthalene was observed at SbF$_5$/substrate molar ratios around 1, but increasing SbF$_5$ content resulted in decreasing selectivity. On the basis of this information, an intracomplex reaction mechanism was suggested [Eq. (5.162)] with the arenium ion protonating CO to form the para-oriented $\pi$-complex 117. At high SbF$_5$/substrate molar ratios, protonated CO (formyl cation) is the actual formylating agent and the regioselectivity reflects the ratio of the two mechanisms.
Unprecedented high ortho selectivities were observed in the monoformylation of bibenzyl in HF–Lewis acid systems (Lewis acid: SbF₅, TaF₅, BF₃, NbF₅) in contrast to biphenyl, diphenylmethane, and 1,3-diphenylpropane. The selectivity increased with decreasing SbF₅/Lewis acid molar ratios, and with the strength of the Lewis acid used. The ortho monoformylation was explained to take place with the participation of the sandwich-like complex 118 formed from the monocation, whereas dication 119 gives the para-diformyl product.

For nearly a century, Friedel–Crafts acylations were considered to give nearly exclusive para substitution of toluene. The reason accounting for this fact was considered to be steric. The present-day understanding of the mechanism of electrophilic aromatic substitution indicates that this is not necessarily the only reason. para Substitution is greatly favored if the transition state of highest energy is an intermediate arenium ion (σ-complex) like, where a para methyl group is more stabilizing than an ortho (and much more than a meta). However, when the highest transition state is becoming increasingly “early” on the reaction path, the ratio of ortho:para substitution increases. meta Substitution always stays relatively low, generally less than 5–6% varying with the reactivity of the reagent within this limit. This substitution pattern is also observed in Friedel–Crafts-type formylation reactions. In these reactions, the involved substituting agents are obviously less space demanding than those of other acylation reactions. Steric effects consequently cannot be a significant factor affecting selectivity, which is primarily reflected in the changing ortho:para isomer ratio. The methyl group always remains predominantly ortho:para directing, even in very low substrate selectivity reactions, and the meta isomer does not increase above 4%.

Regioselective formylation of toluene, meta- and para-xylene, and mesitylene has been achieved by carbonylation in triflic acid at CO pressures of 90–125 atm. However, the use of six- to sevenfold excess of acid over arene is required to obtain high yields of the aldehydes. Recently, a para-tolualdehyde yield of 99.1% has been reported (triflic acid/toluene molar ratio = 20, CO pressure = 70 atm, room temperature, 30 min).
Formylation of the less reactive phenol and anisole with CO in HF–BF₃ was found to require at least stoichiometric amount of the acid for effective transformation (50 equiv. of HF, 2 equiv. of BF₃, 50 bar CO, 45°C). Conversion increases with increasing reaction time but results in decreasing para/ortho ratios suggesting a change from kinetic control to thermodynamic control and the reversibility of formylation. Furthermore, the amount of byproducts (mainly diphenylmethane derivatives) originating from reactions between substrates and products also increases. Additional studies in ionic liquids showed that imidazolium cations with increased chain lengths—for example, 1-octyl-3-methylimidazolium salts—are effective in the formylation process. This was attributed to the enhanced solubility of CO in the ionic liquid medium. Tris(dichloromethyl)amine, triformamide, and tris(diformylamino)methane have recently been applied in the formylation of activated aromatic compounds in the presence of triflic acid at low temperature (−10 to −20°C) albeit yields are moderate.

While studying the reaction of adamantane with carbon monoxide under superacidic catalysis, formylation (formation of 1-adamantane-carboxaldehyde) was found by Olah and co-workers to effectively compete with Koch–Haaf carboxylation (formation of 1-adamantane-carboxylic acid, major product formed in 60–75% yield). On the basis of results acquired by the reaction of 1,3,5,7-tetradedteroadamantane, formylation was interpreted by insertion of the formyl cation into the tertiary C–H σ-bond [Eq. (5.163)].

A more effective formylation of adamantane has been developed by Vol’pin, Akhrem, and co-workers using the aprotic organic superacids CBr₄–2AlBr₃ and CH₂Br₂–2AlX₃ (X = Cl, Br). With methylcyclopentane as the hydride source, 1-adamantanecarboxaldehyde was isolated in 100% yield under optimized conditions (substrate:superacid:methylcyclopentane molar ratio = 1:1:2, CH₂Br₂–2AlCl₃, atmospheric CO pressure, 20°C, 2 h).

Olah et al. have recently described a new, highly efficient superelectrophilic formylation–rearrangement of isoalkanes. Branched ketones are formed in high yields and with high selectivity with no detectable branched acids (Koch products) in the presence of moderately strong superacids such as HF–BF₃ or triflic acid–BF₃. Carbonylation of isobutane under such conditions gives isopropyl methyl ketone in high yield [Eq. (5.164)] The transformation was interpreted with the involvement of
the pentacoordinate carbodication 120a formed by the attack of reactive protosolvated formyl cation \([\text{HC} = \text{COH}]^{2+}\) on the tertiary C–H bond of isobutane. According to subsequent calculations [MP2(full)/6-31G*],\(^{451}\) this species is a minimum on the potential energy surface and can be considered as the enolic form of 2-methylpropanal with a proton on one face and a methyl cation on the other face of the C–C double bond (120c). This dication can rearrange in a single step to a distonic dication, which leads to the final product isopropyl methyl ketone (see Section 5.17.3).

Attempts have been made\(^ {435}\) to observe the long-lived formyl cation under stable ion conditions using \(^{13}\)C-enriched carbon monoxide. However, even at very low temperatures proton exchange with the superacid solvent is fast on the NMR time scale. In a recent study, however, de Rege, Gladysz, and Horváth\(^ {452}\) have observed protonated carbon monoxide by IR and NMR spectroscopy at high CO pressure in HF–SbF\(_5\). They were also able to demonstrate\(^ {453}\) the carbonylation of methane with carbon monoxide under similar conditions (HF–SbF\(_5\) or HSO\(_3\)F–SbF\(_5\), 80°C, pressure), which leads to the exclusive and quantitative formation of the acetylium ion \(\text{CH}_3\text{CO}^+\). Quenching the reaction mixture with water gives acetic acid in quantitative yield.

### 5.6. THIO- AND DITHIOCARBOXYLATION

Aromatic carboxylic acid derivatives are generally prepared by Friedel–Crafts methods using phosgene, oxalyl chloride, or carbamoyl chlorides.\(^ {397}\) Carbon disulfide reacts with arenes in the presence of excess AlCl\(_3\) catalyst to give dithiocarboxylic acids.\(^ {454–456}\) However, these reactions generally require at least 2 mol excess of the strong Lewis acid catalyst, and significant side reactions occur.

Olah et al.\(^ {457}\) have developed a mild method for the preparation of methyl and ethyl thio(dithio)benzoates. They prepared S-methyl (S-ethyl) thiocarboxonium and dithiocarboxonium fluoroantimonates 121a and 121b by methylating (ethylating) carbonyl...
sulfide and carbon disulfide, respectively, with methyl(ethyl)fluoride–antimony
pentfluoride complexes in SO\(_2\) solution [Eq. (5.165)]. Then these reagents were
used under mild conditions for the preparation of methyl and ethyl thio(dithio)
benzoates by electrophilic substitution of aromatic hydrocarbons [Eq. (5.166)].

\end{align*}
\]

60–84% yield

5.7. SULFONATION AND SULFONYLATION

Sulfonation of aromatic compounds is generally carried out with sulfuric acid,
halosulfuric acids, or sulfur trioxide as reagent with or without solvent.\(^{458,459}\)
Friedel–Crafts catalysts such as aluminum chloride and boron trifluoride are effective
catalysts in certain sulfonations with sulfuric acid and chlorosulfuric acid.

When SO\(_3\) is used in fairly dilute solution, the attacking species is SO\(_3\) itself. In
concentrated sulfuric acid, however, the mechanism is more complex. Fuming sulfuric
acid (in which the molar fraction of SO\(_3\) > 0.5) is actually a mixture of SO\(_3\) and ionized
or nonionized monomers, dimers (H\(_2\)S\(_2\)O\(_7\), with), trimers (H\(_2\)S\(_3\)O\(_{10}\)), and tetramers
(H\(_2\)S\(_4\)O\(_{13}\)) of H\(_2\)SO\(_4\) (the latter three formed by dehydration). At higher water content,
the tetramer and trimer disappear and the amount of dimer decreases. The reactive
species in sulfuric acid thus depends on the amount of water in the acid and on the
reactivity of the substrate. The reactive species in aqueous sulfuric acid are H\(_2\)SO\(_4\) and
H\(_2\)S\(_2\)O\(_7\), with the latter being more important at higher acid concentrations. In fuming
sulfuric acid, H\(_3\)S\(_2\)O\(_7^+\) and H\(_2\)S\(_3\)O\(_{13}\) are also involved.\(^{360}\)

Chlorosulfuric acid (HSO\(_3\)Cl) reacts with aromatic hydrocarbons to give sulfonic
acids, sulfonyl chlorides, and sulfones, with the relative yields depending on
the reaction conditions. The reaction with benzene with an equimolar amount of
chlorosulfuric acid in sulfur dioxide as solvent at $-8^\circ$C yields mainly benzene-
sulfonyl chloride is also formed.\textsuperscript{462} Compared with HSO$_3$Cl, HSO$_3$F is a poorer sulfonating agent and tends to give arylsulfonyl fluorides more easily; excess of halosulfuric acids gives halosulfonation.

Studying the formylation of alkylbenzenes in HSO$_3$F–SbF$_5$, Tanaka et al.\textsuperscript{436} have observed both formylation and sulfonation. However, in the presence of HSO$_3$F, that is at low acidity level, only sulfonyl compounds were obtained [Eq. (5.167)], whereas increasing acidity (with added SbF$_5$) resulted in the formation of products of formylation.

(5.167)

Herlem et al.\textsuperscript{463} have observed that asphaltene is dissolved in fluorosulfuric acid and the process is accompanied by strong redox reactions (SO$_2$ and HF evolution). The products are mainly functionalized by SO$_3$H groups, but SO$_2$F groups were also detected by XPS. Indeed, model studies with benzene showed the formation of benzenesulfonic acid, diphenylsulfone, and benzenesulfonyl fluoride. For alkyl-
benzenes, sulfonation was not accompanied by cracking of the alkyl chain.

Nafion-H has also been used as sulfonation catalyst.\textsuperscript{464} When oleum and long-
chain alkylbenzenes were separated from each other by a Nafion-H membrane, the membrane transported the sulfonating agent into the alkylbenzene at a rate convenient for dissipating the heat of the reaction. Reported yields of sulfonation products were 34% (4 h), 63% (6 h), and 86% after 22.5 h.

Friedel–Crafts-type intermolecular sulfonylation of aromatics can also be conven-
tiently carried out over Nafion-H by reacting aromatics with arenesulfonic acids at reflux temperature with azeotropic water removal\textsuperscript{465} [Eq. (5.168)]. Methanesulfonic acid also reacts with \textit{para}-xylene to yield 2-methanesulfonyl-1,4-dimethylbenzene in much lower yield (30%).

\]
Olah et al.\textsuperscript{466} observed immediate formation of protonated benzenesulfinic acid upon addition of SO$_2$ to benzenium ion formed in HSO$_3$F–SbF$_5$–SO$_2$ClF solution at $-78\degree$C. Based upon this observation, Laali and Nagvekar\textsuperscript{467} developed a method for the synthesis of aromatic sulfoxides [Eq. (5.169)]. Product formation was interpreted in terms of dehydration of protonated benzenesulfinic acid followed by nucleophilic attack by the aromatic to the formed arenesulfinyl cation. Mixed sulfoxides (4-fluorophenyl-4-methylphenyl and 4-fluorophenyl-3-trifluoromethyl sulfoxides) were also prepared by sequential addition of the two aromatics. The direct synthesis of symmetric diaryl sulfoxides in high yields (room temperature, 2–48 h, 50–95%) has been reported through the electrophilic activation of thionyl chloride with triflic acid.\textsuperscript{468}

![Reaction scheme for the synthesis of aromatic sulfoxides](image)

Triflic acid itself is a poor catalyst for the sulfonylation of aromatics with arenesulfonyl chlorides to give diarylsulfones. Addition of BiCl$_3$, however, dramatically increases the activity (10 mol\% TfOH, 5 mol\% BiCl$_3$, 120$\degree$C, 65–97\% yields).\textsuperscript{469} A similar synergistic effect has been observed with BiCl$_3$ or SbCl$_3$ in the sulfonylation of both activated and deactivated aromatics with methanesulfonyl chloride\textsuperscript{470} [Eq. (5.170)]. The triflic acid–BiCl$_3$ system (10 mol\% each) proved to be more efficient in most cases; however, only the triflic acid–SbCl$_3$ system could be used for fluorinated arenes because of solubility reason. The actual active species was suggested to be the mixed anhydride MeSO$_2$OTf.

![Reaction scheme for the synthesis of diarylsulfones](image)
5.8. NITRATION

Convenient nitration of aromatic compounds is carried out using a mixture of nitric acid and sulfuric acid (mixed acid). There are, however, difficulties associated with the use of mixed acid.\(^{459,471-473}\) In particular, the water formed as the reaction proceeds dilutes the acid and therefore reduces its strength. Also, the strong oxidizing ability of a mixed acid system makes it unsuitable to nitrate many acid-sensitive compounds. The disposal of the spent acid also poses a significant environmental problem. To overcome these difficulties of anhydrous Friedel–Crafts-type nitrations catalyzed by strong acids, nitronium salts (such as NO\(_2^+\)BF\(_4^-\), NO\(_2^+\)PF\(_6^-\), NO\(_2^+\)SbF\(_6^-\), etc.) were developed\(^{474}\) which are extremely powerful nitrating agents.

Stable nitronium salts, which are readily prepared from nitric acid (or nitrates) with HF and BF\(_3\) (and other Lewis acids such as PF\(_5\), SbF\(_5\), etc.) \([\text{Eqs. (5.171) and (5.172)}]\), will nitrate aromatics in organic solvents generally with close to quantitative yield.\(^{472,473}\) Because HF and PF\(_5\) (or BF\(_3\)) can be easily recovered and recycled, the method can be considered as a nitric acid nitration using a superacid catalyst \([\text{Eq. (5.173)}]\).

\[
\begin{align*}
\text{HNO}_3 + \text{HF} + 2 \text{BF}_3 & \rightarrow \text{NO}_2^+ \text{BF}_4^- + \text{BF}_3\text{–OH}_2 \quad (5.171) \\
\text{RONONO}_2 + \text{HF} + 2 \text{BF}_3 & \rightarrow \text{NO}_2^+ \text{BF}_4^- + \text{BF}_3\text{–ROH} \quad (5.172) \\
\text{ArH} + \text{NO}_2^+ \text{MF}_{n+1}^- & \rightarrow \text{ArNO}_2 + \text{HF} + \text{MF}_n \\
\text{MF}_{n+1} = \text{BF}_4, \text{PF}_6
\end{align*}
\]

The powerful nature of nitronium salts as nitrating agents is demonstrated in their ability to affect even trinitration of benzene to trinitrobenzene \([\text{Eq. (5.174)}]\).\(^{475}\) Nitronium salts enable nitration of every conceivable aromatic substrate.

\[
\begin{align*}
\text{NO}_2^+ \text{BF}_4^- \quad \text{HSO}_3\text{F} & \rightarrow \text{ArNO}_2 + \text{O}_2\text{N} + \text{NO}_2
\end{align*}
\]

The powerful nitronium salts are also capable of reacting with aliphatics. Electrophilic nitration of alkanes and cycloalkanes has been carried out with NO\(_2^+\)PF\(_6^-\), NO\(_2^+\)SbF\(_6^-\), or NO\(_2^+\)BF\(_4^-\) salts in CH\(_2\)Cl\(_2\)–tetramethylenesulfolane or HSO\(_3\)F solution.\(^{476}\) Table 5.31 lists some representative reactions of nitronium ion with various alkanes and cycloalkanes. The formation of nitroaliphatics indicates the insertion of nitronium ion into aliphatic \(\sigma\)-bonds involving two-electron, three-center-bonded five-coordinate carbocations as indicated in the nitration of adamantane\(^{477}\) \([\text{Eq. (5.175)}]\).
Nitronium ion, which is linear with \(sp\)-hybridized nitrogen, is not very reactive in aprotic media and not capable of nitrating deactivated aromatics. The reactivity of nitronium salts, however, can be further increased, when nitration is carried out in superacid solution (HF, HSO\(_3\)F). The enhanced reactivity is attributed to protosolvation, \(3^-5\)—that is, to the formation of protonitronium dication \([\text{Eq. (5.176)}]\), suggested as early as 1975 by Olah et al.\(^1\) The interaction of the superacid with the nitronium ion weakens the N–O \(\pi\)-bond character, resulting in the bending of the linear ion and rehybridization of the N from \(sp\) to \(sp^2\). Nitronium salts under superacidic conditions were shown to react even with methane proceeding through the 3\(c–2e\) bound carbocation transition state formed by the insertion of protonitronium dication \(122\) into the C–H bond\(^476\) [Eq. (5.177)].

\[
\begin{align*}
\text{CH}_4 + \text{NO}_2^+ & \rightleftharpoons \text{CH}_3\text{NO}_2 + \text{H}^+ \quad \text{(5.175)} \\
\text{CH}_3\text{NO}_2 + \text{H}^+ & \rightleftharpoons \text{CH}_3\text{NO}_2\text{H}^+ \quad \text{(5.177)}
\end{align*}
\]

This has been demonstrated in a comparative study\(^479\) using nitronium salts in the nitration of deactivated polyfluoronitrobenzenes performed in dichloromethane and sulfolane, as well as triflic acid. When 2,4-difluoronitrobenzene, 2,3,4-trifluoronitrobenzene, and 1,3,5-trifluoronitrobenzene were reacted with NO\(_2^+\)BF\(_4^-\) in
sulfolane at 70°C, no product was formed, whereas 2,4-difluoronitrobenzene and 1,3,5-trifluorobenzene gave the corresponding nitrated derivative in dichloromethane under reflux (30% and 90% yield, respectively). In contrast, all model compounds underwent nitration in triflic acid at 70°C; moreover, 1,3,5-trifluorobenzene gave the dinitro derivative (yields are 34%, 65%, and 29%). In addition to better solubility and higher dissociation of the nitronium salt, the enhanced reactivity was attributed to protosolvation of the NO$_2^+$ ion by the superacid.

Olah et al.\textsuperscript{480} have found that nitration of aromatics with potassium nitrate or nitric acid catalyzed by boron trifluoride–monohydrate BF$_3$–H$_2$O proceeds with good to excellent yield and is capable of nitrating even some deactivated aromatics [Eq. (5.178)]. Later, it was shown that potassium nitrate with the complex boron trifluoride–trifluoroethanol BF$_3$–2CF$_3$CH$_2$OH is equally effective\textsuperscript{481} [Eq. (5.178)].

Nitration of strongly deactivated aromatics was carried out with nitric acid mixed with triflatoboric superacid.\textsuperscript{482} The method is characterized by high yields (pentafluorobenzene, 99%; 1,2,3,5-tetrafluorobenzene, 89%; 2,3,4-trifluoronitrobenzene, 96%; methyl phenyl sulfone, 78%), usually high regioselectivity, and mild reaction conditions (room temperature), and it also tolerates many functional groups.

The anhydride of nitric acid and triflic acid prepared according to Eq. (5.179) was also shown to be a highly effective nitrating agent in various solvents (nitromethane, nitroethane, CFCl$_3$) to afford nitro products in high yields (67–99%).\textsuperscript{483} According to $^{15}$N NMR spectroscopy of $^{15}$N-enriched nitric acid in triflic acid, trifluoromethanesulfonil nitrate formed is predominantly covalent in nature. However, triflic acid formed in the system allows protolytic cleavage of the O–NO$_2$ bond. Competitive nitration of benzene–toluene mixtures may shed light to the nature of the nitrating agent. Preformed, highly reactive nitronium salts, in general, show very low substrate selectivity ($k_T/k_B < 2$), whereas less reactive covalent nitrates exhibit higher $k_T/k_B$ values (nitric acid/acetic acid, 24; trifluoroacetyl nitrate, 28). The value for nitric acid/triflic anhydride (benzene–toluene, 1:1 molar ratio) is 36. Kinetic studies of nitration with nitric acid in neat triflic acid and over triflic acid on silica showed\textsuperscript{484,485} that triflic acid is less effective in nonaqueous solution, which is attributed to ion pairing and strong interaction between ionic species.

\[
\text{(CF}_3\text{SO}_2\text{)}_2\text{O} + \text{HNO}_3 \quad \rightarrow \quad \text{CF}_3\text{SO}_3\text{NO}_2 + \text{CF}_3\text{SO}_3\text{H} \quad \text{(5.179)}
\]
Nitronium tetrafluoroborate used in large excess (>6 equiv.) is able to transform hexamethylbenzene and its derivatives to dinitrophenitene (1,2,3,4-tetramethyl-5,6-dinitrobenzene) in a highly selective nitration process\(^\text{486}\) [Eq. (5.180)]. Scheme 5.47 summarizes the key steps of the mechanistic proposal, including the ipso-nitroareniun ion 123, the formation of benzyl nitrite 124, and the complexation of the \(\text{NO}_2^+\) ion to form the mononitro intermediate (125) facilitating the attack to the ortho position resulting in the formation of the 1,2-dinitro product.

\[
\begin{align*}
R^+ & \quad \text{NO}_2^+ \quad \text{BF}_4^- \\
& \quad \text{CH}_2\text{Cl}_2, \text{RT, 10 h} \\
& \quad 90-96\% \text{ yield}
\end{align*}
\]

(5.180)

Excellent results have been reported on the nitration with the \(\text{NO}_2\text{Cl}–3MX_n\) (\(X_n = \text{AlCl}_3, \text{SbCl}_3\)) superelectrophilic aprotic nitrating agent.\(^\text{487}\) Strongly deactivated arenes, including benzo trifluoride, polyhalogenated arenes, and aroyl derivatives, give the corresponding nitro derivatives in high, often quantitative yields under mild conditions (\(\text{CH}_2\text{Cl}_2, 0–20^\circ\text{C}\)) in short reaction times (15–180 min).
Nitronium ions such as \( N \)-nitropyridinium salts, which are readily prepared from the corresponding pyridine and nitronium salts,\(^{488,489}\) act as convenient transfer nitrating agents. Transfer nitrations are applicable to \( C \)-nitrations [Eq. (5.181)] as well as to a variety of heteroatom nitrations. For example, they allow safe, acid-free preparation of alkyl nitrates and polynitrates from alcohols (polyols) in nearly quantitative yield\(^{490}\) [Eq. (5.182)].

\[
\begin{align*}
\text{R} &= 2\text{-Me, 2,6-diMe, 2,4,6-triMe,} \\
\text{X} &= \text{PF}_6^-, \text{BF}_4^- \\
\end{align*}
\]

\[(5.181)\]

Electrophilic nitration of olefins can also be carried out with nitronium salts in pyridinium poly(hydrogen fluoride) (PPHF) solution\(^{491}\) (which also acts as solvent) to give high yields of nitrofluorinated alkanes. In the presence of added halide ions (iodide, bromide, chloride) the related haloalkanes are formed, and these can be dehydrohalogenated to nitroalkenes\(^{492}\) [Eq. (5.183)].

\[
\begin{align*}
\text{R} &= \text{H, Me, iso=Pr, tert-Bu} \\
\end{align*}
\]

\[(5.182)\]

Originally, the nitronium ion was recognized only as a nitrating agent.\(^{493}\) Subsequently, it was found\(^{494-496}\) to possess significant ambident reactivity and thus be capable of acting as an oxidizing agent. Dialkyl (diaryl) sulfides [Eq. (5.184)] and selenides [Eq. (5.185)] as well as trialkyl (triaryl) phosphines
[Eq. (5.186)], triaryl arsines, and triaryl stibines react with nitronium salts to give the corresponding oxides.

\[
\begin{align*}

X &= \text{P, As, Sb}
\end{align*}
\]

Stable nitronium \(\text{(NO}_2^+\) salts, particularly with \(\text{PF}_6^-\) and \(\text{BF}_4^-\) counterions, can act as mild, selective oxidative cleavage reagents for a wide variety of functional groups.\textsuperscript{497–499} Examples such as the oxidation of methyl ethers [Eq. (5.187)], oximes [Eq. (5.188)], dimethylhydrazones [Eq. (5.189)], and thioacetals [Eq. (5.190)] illustrate the utility of these methods.

\end{align*}
\]
Bicyclo[2.2.1]heptane (norbornane) and bicyclo[2.2.2]octane, when treated with nitronium tetrafluoroborate in nitrile-free nitroethane, unexpectedly gave no nitro products. Instead, only bicyclo[2.2.1]heptane-2-one and bicyclo[2.2.2]octan-1-ol were isolated, respectively.\textsuperscript{500} Observation of bicyclo[2.2.1]heptane-2-yl nitrite as an intermediate and additional information led to the suggestion of the mechanism depicted in Scheme 5.48. In the transformation of norbornane the first intermediates are the 2-norbornyl cation \textsuperscript{126} formed by hydride abstraction and nonclassical cation \textsuperscript{127} formed through insertion of \( \text{NO}_2^+ \) into the secondary C–H bond. In the case of bicyclo[2.2.2]octane, the oxidation of bridgehead tertiary C–H bond takes place and no further transformation can occur under the reaction conditions. Again these electrophilic oxygenation reactions testify to the ambident character of the nitronium ion.

Mononitro compounds could be selectively obtained in the nitration of phenylpropioinic acid derivatives with HNO\(_3\)–HSO\(_3\)F at low temperature\textsuperscript{501} [Eq. (5.191)]. Addition of fluorosulfuric acid to the triple bond, however, may also take place with substituted derivatives.

The nitrolysis of the highly energetic \textit{gem}-bisfluoroamino) derivative \textsuperscript{128} has proved to be difficult.\textsuperscript{502} The functionalization of the sterically hindered amido groups
with HNO₃–triflic acid required long reaction time at elevated temperature [Eq. (5.192)]. Addition of SbF₅ to the nitrating system, in turn, resulted in a faster reaction under milder conditions.

\]

128 65% yield

The solid superacidic Nafion-H has also been found to catalyze effectively nitration reactions with various reagents.⁵⁰³ The nitrating agents employed were \( n \)-butyl nitrate, acetone cyanohydrin nitrate, and fuming nitric acid. In nitric acid nitrations, sulfuric acid can be substituted by Nafion-H and the water formed is azeotropically removed during the reaction (azeotropic nitration).⁵⁰³

Nitrobenzene was also prepared in a liquid flow system using a hollow tube of Nafion-H membrane. Benzene was passed over the outside of tube containing 70% nitric acid. The yield of nitrobenzene was 19%.⁵⁰⁴ The nitration of aromatic compounds has also been carried out with Nafion-H in the presence of mercury nitrate as well as Hg²⁺-impregnated Nafion-H catalyst.⁵⁰⁵ These studies indicated that Nafion-H–HNO₃ and Nafion-H–(HNO₃)Hg²⁺ nitrate by different mechanisms. It was proposed that the mercury-containing catalyst operates in part by mercurating the arene followed by nitrodemercuration of the initial product.

Generally, nitration of aromatic compounds is considered to be an irreversible reaction. However, the reversibility of the reaction has also been demonstrated.⁵⁰⁶ 9-Nitroanthracene and pentamethylnitrobenzene transnitrate benzene, toluene, and mesitylene in the presence of HF–SbF₅ as well as Nafion-H [Eq. (5.193)].

\]

5.9. NITROSONIUM ION (NO⁺)-INDUCED REACTIONS

Nitrosonium ion (NO⁺) is the electrophilic species formed from nitrous acid media, which is responsible for such reactions as diazotization of amines. Nitrosonium ion has
been isolated as salts with a wide variety of counterions such as BF$_4^-$, PF$_6^-$, and SbCl$_6^-$. The nitrosonium ion does not react with aromatics except in the case of activated systems (such as N,N-dimethylaniline or phenols). $^{507,508}$ Frequently, they form colored π-complexes. Nitrosonium ion is a powerful hydride abstracting agent. Cumene reacts with NO$^+$ to give various condensation products, which involves intermediate formation of cumyl cation. $^{509}$ Similarly, the nitrosonium ion is employed in the preparation of a variety of stabilized carbocations. $^{510}$ Some of the reactions of nitrosonium ion are depicted in Scheme 5.49. $^{492}$

The hydride abstraction reaction of NO$^+$ has been employed in a modified Ritter-type reaction $^{511}$ (Scheme 5.50, route $a$) as well as in ionic fluorination $^{512}$ of bridgehead hydrocarbons (Scheme 5.50, route $b$).
Similarly, NO$^+$ is also capable of halogen abstraction from alkyl halides.$^{513,514}$ In the presence of a suitable oxygen donor such as dimethylsulfoxide, nitrosonium ion can act as a nitrating agent$^{493,494}$ [Eq. (5.194)].

$$\begin{array}{c}
\text{Me}^+ - \text{S}^- \text{O}^- + \text{NO}^+ \rightleftharpoons \text{Me}^+ - \text{S}^- \text{ONO} \rightleftharpoons \text{Me}^+ - \text{S}^- \text{NO}_2 \overset{\text{-Me}_2\text{S}}{\rightarrow} \text{ArNO}_2 \\
\end{array}$$

(5.194)

Nitrosonium ion can also act as a mild and selective oxidizing agent. It has been used to cleave oxidatively oximes, hydrazone,$^{498}$ and thioetals to their corresponding carbonyl compounds,$^{499}$ to cleave benzylic esters$^{515}$ [Eq. (5.195)], and to oxidize $O$-tributylstannyl and $O$-trimethylsilyl ethers and benzylic alcohols$^{516}$ [Eq. (5.196)].

$$\begin{array}{c}
\text{R} - \text{C} - \text{O} \overset{\text{NO}^+ \text{PF}_6^-}{\longrightarrow} \text{H}_2\text{O} \rightarrow \text{R} - \text{C} - \text{O} \\
\text{R} = \text{C}_{10}\text{H}_{21}, \text{cyclo-C}_6\text{H}_{11}\text{Ph}, \\
\text{4-ClC}_6\text{H}_4, \text{4-MeOC}_6\text{H}_4 \\
\text{Ar} = \text{Ph}, \text{benzhydryl} \\
\end{array}$$

\text{4-ClC}_6\text{H}_4, \text{4-BrC}_6\text{H}_4$
Nitrosonium ion was found to insert into the Cr–C bond\(^{518}\) [Eq. (5.198)] and into the C–C bond of the cyclopropane ring\(^{519}\) [Eq. (5.199)]. The latter reaction opens up a new route to 2-oxazolines. On the basis of experimental observations, particularly the similarity of product distributions in the analogous photoinsertion of NO, the involvement of the intermediate cationic species 129 and 130 was suggested.

\end{align*}
\]

\[\text{Eq. (5.200)}\]

The same reagent combination—that is, \(\text{NO}^{+}\text{BF}_{4}^{-}\) (used in an excess of 1.2 equivalent) in conjunction with PPHF—also induces desulfurative fluorination of phenylsulfides\(^{521}\) (Scheme 5.51). A possible mechanism includes the intermediate cation 131, which undergoes fluorination via an \(S_{N}2\) or \(S_{N}1\) pathway. Dithiolanes,
under the same conditions (NO\(^+\)BF\(_4^−\) in an excess of 2.2 equivalents), afford the corresponding gem-difluorides [Eq. (5.201)].

\[
\begin{align*}

\end{align*}
\]

5.10. HALOGENATION

5.10.1. Halogenation of Nonaromatic Compounds

The halogenation of saturated aliphatic hydrocarbons is usually achieved by free radical processes.\(^{523}\) Ionic halogenation of alkanes has been reported under superacid catalysis. Olah and co-workers\(^{524,525}\) have carried out chlorination and chlorolysis of
alkanes in the presence of SbF$_5$, Al$_2$Cl$_6$, and AgSbF$_6$ catalysts. As a representative, the reaction of methane with Cl$_2$–SbF$_5$ is depicted in Scheme 5.52. The results of AgSbF$_6$-catalyzed chlorination are shown in Table 5.32. Subsequently, selective ionic chlorination of methane to methyl chloride was achieved in the gas phase over solid superacid catalysts.$^{526}$ For example, chlorination of methane in excess chlorine over Nafion-H and SbF$_5$–graphite gave methyl chloride with 88% and 98% selectivity, respectively (185°C and 180°C, 18% and 7% conversion).$^{527}$ Similarly, electrophilic bromination of alkanes has also been carried out$^{528}$ (Scheme 5.53).

\[
\begin{array}{c}
\text{Br}_2 + \text{AgSbF}_6 \rightarrow \delta^+ \text{Br} - \text{Br} \rightarrow \delta^- \text{AgSbF}_6 \\
R_3\text{C} - \text{H} + \delta^+ \text{Br} - \text{Br} \rightarrow \text{AgSbF}_6 \rightarrow \left[ \begin{array}{c} \\
H \\
R_3\text{C} \end{array} \right]^+ + \text{AgBr} \\
\rightarrow R_3\text{C} - \text{Br} + \text{H}^+ \text{SbF}_6^- \\
\end{array}
\]

Scheme 5.53

Even electrophilic fluorination of alkanes is possible. F$_2$ and fluoroxytrifluoromethane have been used to fluorinate tertiary centers in steroids and adamantanes by Barton and co-workers.$^{529}$ The strong influence of electron-withdrawing substituents on the reaction rate, as well as reaction selectivity, in the presence of radical inhibitors seems to suggest the electrophilic nature of the reaction involving polarized, but not cationic, fluorine species. Claims for the latter have been refuted.$^{530}$ Gal and Rozen$^{531,532}$ have carried out direct electrophilic fluorination of hydrocarbons in the presence of chloroform. Fluorine appears to be strongly polarized in chloroform (hydrogen bonding with acidic proton of chloroform). However, positively charged fluorine species (i.e., fluoronium ions) are rare, and only a few examples are known in solution chemistry (see Section 4.2.4.2).

Olah, Prakash, and co-workers$^{533}$ have reported the electrophilic fluorination of methane with N$_2$F$^+$ and NF$_4^+$ salts serving as “F$^+”$ equivalents in pyridinium
poly(hydrogen fluoride) (PPHF) [Eq. (5.203)]. Exclusive formation of methyl fluoride was observed with NF₄⁺SbF₆⁻ in a large excess of methane (16 equivalents), whereas the other two reagents (NF₄⁺AsF₆⁻ and N₂F⁺AsF₆⁺) gave methyl fluoride with high selectivity in a methane excess of 4. Calculations with respect to a model of the CH₄ + F⁺ reaction (QCISD/6-31G*//QCISD/6-31G* + ZPE level) showed that structure 132 (a complex between CH₃⁺ and HF) is a global minimum on the potential energy surface. It is 27.7 kcal mol⁻¹ more stable than structure 133.
(a loose complex between $\text{CH}_2\text{F}^+$ and $\text{H}_2$). Formation of cation 132 from $\text{CH}_4$ and $\text{F}^+$ is exothermic by 293.1 kcal mol$^{-1}$.

$$\text{CH}_4 + \text{"F"}^+ \xrightarrow{\text{HF or PPHF}} \text{CH}_3\text{F} + \text{CH}_2\text{F}_2 + \text{CHF}_3$$

Nonactivated C–H bonds in imines can be selectively monofluorinated in HF–SbF$_5$ in the presence of CCl$_4$ to yield the corresponding fluoroketones when the reaction mixture is quenched with HF–pyridine$^{534}$ (Scheme 5.54). The transformation is initiated by hydride abstraction with CCl$_3^+$ from the most reactive carbon farthest from the functional group and involves dicationic intermediates 134 and 135.

Selective monohalogenation (chlorination and bromination) can be accomplished with excess methylene halides in the presence of SbF$_5$. Adamantane, for example, gives 1-chloroadamantane in 80% yield at ambient temperature in 24 h.
Propane and cyclopentane give isopropyl chloride and cyclopentyl chloride, respectively, whereas isobutane is transformed to tert-butyl chloride under the same reaction conditions (yields are 69%, 74%, and 76%, respectively). Neopentane undergoes isomerization to yield 2-chloro-2-butane (88%). When saturated, hydrocarbons were allowed to react with methylene bromide and SbF$_5$ bromoalkanes were obtained in comparable yields (64–75%). Formation of the halogenated product can be best explained by the mechanistic pathway (I) depicted in Scheme 5.55. Since SbF$_5$ always contains some HF, mechanism (II) may also contribute to product formation (Scheme 5.55).

The aprotic organic superacid systems polyhalomethane–nAlX$_3$ (X = Cl, Br) developed by Vol’pin, Akhrem, and co-workers$^{536–538}$ can promote ionic halogenation of saturated hydrocarbons. The bromination of ethane catalyzed by CBr$_4$–2AlBr$_3$ leads to the formation of 1,2-dibromoethane with high selectivity (55–65°C, CH$_2$Br$_2$ solution or solvent-free conditions). Propane yields isopropyl bromide selectively, whereas butane gives isomeric monobromides at −20°C. Cycloalkanes (cyclopentane, cyclohexane, methylcyclopentane) can be monobrominated effectively and selectively at −20°C. Saturated hydrocarbons (propane, cyclopentane, cyclohexane, norbornane, adamantane) also undergo moniodination with I$_2$ in the presence of CCl$_4$–2AlI$_3$ (CH$_2$Br$_2$ solution, −20°C, 1.5–2 h, 50–79% yield).$^{539}$ The related superacid system AcBr–2AlX$_3$ (X = Cl, Br) is able to effectively promote selective monobromination of C$_4$–C$_7$ alkanes and cycloalkanes with molecular bromine between −20°C and 20°C.$^{540}$ Surprisingly, AlBr$_3$ alone with Br$_2$ also exhibits activity in bromination.

1-Bromopropargylic imides [Eq. (5.204)] and amines can be transformed to the corresponding fluoromethyl derivatives in HF–SbF$_5$.$^{541}$ The reaction is fast but in some cases affords a mixture of CF$_2$Br- and CF$_3$-substituted products. Subsequent treatment with HF–pyridine, however, allows complete bromine–fluorine exchange to get the trifluoromethyl derivatives in high yields (60–96%). A new synthesis of trifluoroalkanes from 1,1-dichloro-1-alkenes under similar conditions has recently been reported.$^{542}$ HF in high excess in combination with SbCl$_5$ transforms 1,3-bis(trichloromethyl)benzene to 1,3-bis(trifluoromethyl)benzene in  

\[

\]

Scheme 5.55
high yield (80%) with high selectivity (99%) (50°C, 1 h).\textsuperscript{543} With increasing temperature, redistribution of halogen atoms in the partially fluorinated products becomes significant to form the starting material and the hexafluorinated product. 1-Trichloromethyl-3-trifluoromethylbenzene, the most desired product, can be produced with the highest selectivity in the presence of HF alone. Complete halogen exchange in chloromethoxybenzene is also achieved with HF and a catalytic amount of SbCl\textsubscript{5}.\textsuperscript{544}

The HF–SbF\textsubscript{5} superacid finds numerous additional useful applications in other fluorination reactions. Allylic amines are hydrofluorinated in HF–SbF\textsubscript{5} (7:1) to give β-fluoro-substituted products (−20°C, 24–85% yields).\textsuperscript{545} HF–SbF\textsubscript{5} in combination with N-bromosuccinimide transforms allylic amines and haloalkyl amines into gem-difluoro derivatives (0°C or 20°C, 43–70% yield).\textsuperscript{546}

In a search for new fluorinated compounds with biological activity, Jacquesy and co-workers have reported in a series of papers the fluorination of various Cinchona and Vinca alkaloids and derivatives under superacid conditions. When quinidinone was treated in HF–SbF\textsubscript{5} at −78°C, the single monofluoro compound 137 was isolated in 90% yield\textsuperscript{547} [Eq. (5.205)]. The reaction is interpreted by invoking the formation of the intermediate cyclic carboxonium ion 136, which undergoes a concerted rearrangement (ring enlargement) and fluorination to give the final product [Eq. (5.205)].

\textsuperscript{652} SUPERACID-CATALYZED REACTIONS
Quinine acetate, 9-epiquinine, and 9-epiquinine acetate give complex mixtures upon treatment in HF–SbF₅ at −30°C. In the presence of a chloride source (2 equivalents of CCl₄ or reacting the dihydrochlorides), however, equal amounts of two 10,10-difluoro derivatives, epimeric at C(3), could be isolated in 60% yield. The suggested mechanism, shown in Scheme 5.56 for 9-epiquinine, implies that dication 138a formed by protonation undergoes isomerization to give dication 138b epimeric at C(3). The ions are trapped by the complex SbF₅Cl⁻ to form epimeric intermediates chlorinated at C(10). This is followed by hydride abstraction, reaction with F⁻, and finally halogen exchange to give the 10,10-difluorinated products (139; only one of the epimers is shown).

Likewise, dihydrochlorides of quinidine and epiquinidine acetate give epimeric 10,10-difluoro derivatives in HF–SbF₅ in the presence of CCl₄ (39% and 30%,
The pathway given in Scheme 5.56 can also explain the formation of these products. In addition, however, rearranged difluoro derivatives were also obtained in 46% and 45% yield, respectively. This novel rearrangement shown for quinidine acetate (Scheme 5.57) involves 1,2- and 1,3-hydride shifts and a carbon shift.

Two dimeric Vinca alkaloids, vinorelbine and anhydrovinblastine, have also been investigated using the CHCl₃–HF–SbF₅ system. In both cases, the corresponding products difluorinated in the ethyl side chain (140) were isolated in modest yields [Eq. (5.206)]. The mechanistic pathway suggested that the transformation includes steps already depicted in Schemes 5.57 and 5.58.

\[
\begin{align*}
\text{Ar} & = 6' \text{-Me-O-quinolin-4’-yl} \\
\text{Scheme 5.57}
\end{align*}
\]
Stable dialkyl ether poly(hydrogen fluoride) complexes have been shown to be convenient and effective fluorinating agents. Various open-chain and cyclic alkenes undergo hydrofluorination with dimethyl ether–5 HF (DMEPHF) at room temperature to furnish the corresponding fluoro derivatives in high yields (73–94%) with excellent selectivities. The fluorination of secondary and tertiary alcohols exhibit similar features. Bromofluorination of alkenes can also carried out with DMEPHF in combination with N-bromosuccinimide. The homologous diethyl ether and dipropyl ether complexes are also suitable for fluorinations.

5.10.2. Halogenation of Aromatic Compounds

The halogenation of a wide variety of aromatic compounds proceeds readily in the presence of ferric chloride, aluminum chloride, and related Friedel–Crafts catalysts. Halogenating agents generally used are elemental chlorine, bromine, or iodine and interhalogen compounds (such as iodine monochloride, bromine monochloride, etc.). These reactions were reviewed and are outside the scope of the present discussion.

Generally, electrophilic halogenation of phenols leads to the corresponding ortho- and para-substituted products. The synthesis of meta-substituted products is considered difficult.

Jacquesy et al. have succeeded in preparing meta-bromophenols from phenols using the Br₂–HF–SbF₅ system. The ortho-protonated phenol or alkyl phenyl ether, which is in equilibrium with the neutral precursor, reacts with the reactive Br⁺ in the HF–SbF₅ medium, leading to only meta-brominated phenols (Scheme 5.59). The ring protonated phenols are unreactive toward electrophilic bromine in the superacid
medium. Subsequently, the mechanism of isomerization of ortho- and para-
bromophenols to meta-bromophenols using HF–SbF$_5$ and CF$_3$SO$_3$H superacid sys-
tems were also studied.$^{557,558}$ The Br$_2$–HF–SbF$_5$ system was also applied in the
bromination of 2,3-dihydro-$1H$-indoles and 1,2,3,4-tetrahydroquinoline to yield
isomeric monoboromo derivatives with the bromine always occupying meta positions
from the N atom (ortho or para to the side chain).$^{559}$

Later, Sommer and co-workers$^{560}$ used NaBr in HF–SbF$_5$ to brominate anisole
and isomeric methylanisoles. High meta selectivity was observed only for para-
methylanisole. A comparative kinetic study showed that bromine is more effective
(faster reaction, higher yields) than the NaBr–HF–SbF$_5$ system, but the product
distribution is practically the same. Upon dissolution of NaBr in HF–SbF$_5$, a strong red
color developed and SbF$_3$ was also detected. On the basis of these observations, the
involvement of Br$_2^+$ formed via oxidation with SbF$_5$ was suggested.

Jacquesy and co-workers$^{561}$ have reacted aniline with Br$_2$ in the presence HF–SbF$_5$
and isolated monobrominated anilines (ortho/metal/para = 3:24:50). Isomerization
was not observed under the reaction conditions (–40°C), but the products equilibrate
at room temperature through 1,2-Br shift. Dibromination yields 2,5-dibromoaniline
(10%) and 3,4-dibromoaniline (55%), with the second bromination being controlled
by the first bromine introduced.

para-Alkylphenols (para-cresol, indan-5-ol, 6-hydroxytetralin) or methyl ethers
can be transformed to 4-chloro-2,5-cyclohexadienones via ipso-chlorination with the
polychloromethane–SbF$_5$ system (–55 to 0°C, 1.5–90 min, 43–92% yield).$^{562}$ Chloro-
omethyl cations (CICH$_2$)$_2$Cl$^+$, CHCl$_2^+$, and CCl$_3^+$, formed in situ from methylene
chloride, chloroform, and carbon tetrachloride, respectively, induce electrophilic
chlorination to yield ionic species $^{141}$ characterized by NMR spectroscopy
[Eq. (5.207)].
In 1993, Olah, Prakash, and co-workers\textsuperscript{563} reported the ability of \textit{N}-iodosuccinimide (NIS) to efficiently iodinate deactivated aromatics in the presence of triflic acid. Deactivated arenes, such as nitrobenzene, halogenated nitrobenzenes, trifluoromethylbenzene, polyhalogenated benzenes, acetophenone, and benzophenone, react readily with NIS in triflic acid (two- or fivefold excess) to give the corresponding iodoarenes in good yields (53–91\%) under mild conditions (room temperature, 2 h). The $^{13}\text{C}$ NMR spectrum of NIS–triflic acid showed carbonyl resonances at $\delta^{13}\text{C}$ 189 and 192 deshielded by 11 ppm from the corresponding peak in NIS. This indicates the presence of both protonated NIS and succinimide \[\text{Eq. (5.208)}\]. The de facto iodinating agent is suggested to be protosolvated superelectrophilic iodine(I) triflate 142.

Later, the reagent combination \textit{N}-halosuccinimides with BF$_3$–H$_2$O were found to exhibit similar efficiency in chlorination, bromination, and iodination of aromatics\textsuperscript{564} \[\text{Eq. (5.209)}\]. Even pentafluorobenzene could readily be halogenated in high yields (83–96\%). Most reactions are performed under mild conditions; however, chlorination and bromination of nitro compounds required elevated temperature (100–105°C). DFT calculations (B3LYP/6-311++G**//B3LYP/6-31G* level) for \textit{N}-chlorosuccinimide suggest that multiple protonation can take place at increasing
acidities, which may lead to ring opening to reduce internal Coulombic repulsion. The most stable structure with intact ring was found to be dication 143, which is slightly less stable than the ring-opened dication 144. Increasing degree of protonation of the reagent leads to higher degree of charge–charge repulsion, that is, increasing destabilization. Consequently, ground-state destabilization is the driving force to transfer the $X^+$ moiety to the aromatic nucleophile.

\[ \text{N} \quad \text{O} \quad \text{X} \quad + \quad \text{R} \quad \text{R'} \quad \frac{\text{BF}_3 \cdot \text{H}_2\text{O}}{\text{RT}, 0.25\text{–}72\text{ h}} \quad \text{R} \quad \text{R'} \]

\[ \begin{align*}
\text{R} &= \text{F, Cl, Br, I, NO}_2 \\
\text{R'} &= \text{2-F, 4-F, 3-Br} \\
\text{X} &= \text{Cl, Br, I}
\end{align*} \]

Barluenga et al.\textsuperscript{565} have reported the selective monoiridination of arenes with bis (pyridine)iodonium(I) tetrafluoroborate $[\text{I(py}_2\text{)}\text{BF}_4]$ in excess superacids (2 equiv.) [Eq. (5.210)]. Comparable results were found for activated compounds with both HBF$_4$ and triflic acid, whereas triflic acid was more effective in the iodination of deactivated aromatics. For example, nitrobenzene and methyl benzoate are unreactive in HBF$_4$ but give the corresponding iodo derivatives in triflic acid (83% and 84% yields, respectively, in 14 h). Iodination of phenol required low temperature ($-60^\circ\text{C}$).

\[ \text{R} \quad \text{R'} \quad + \quad \text{I(py}_2\text{)}\text{BF}_4 \quad \text{catalyst} \quad \frac{\text{CH}_2\text{Cl}_2, \text{RT}, 6\text{ min}\text{–}45\text{ h}}{} \quad \text{R} \quad \text{R'} \]

\[ \begin{align*}
\text{R} &= \text{H, Me, tert-Bu, OH, MeO, Cl, Br, NH}_2, \text{NMMe}_2, \text{NO}_2, \text{CHO, COOH} \\
\text{R'} &= \text{H, 3-Me, 2-NO}_2, \text{4-Br} \\
\text{2,3-diMe, 3,5-diMe, 3,5-diMeO,}
\end{align*} \]
5.11. AMINATION

Electrophilic amination of aromatics is not a widely used reaction. However, attempts have been made with reagents such as hydroxyl ammonium salts,\textsuperscript{566–571} hydroxylamine-O-sulfonic acid,\textsuperscript{572,573} hydrazoic acid,\textsuperscript{574–576} and organic azides,\textsuperscript{577–580} mostly under Lewis acid-catalyzed conditions (and also with thermal initiation\textsuperscript{581–587} or photolysis\textsuperscript{588,589}). Kovacic and co-workers\textsuperscript{590,591} have found that haloamines can be used as reagents for aromatic amination giving preferential meta substitution in the presence of large excess of AlCl\textsubscript{3} catalyst. They have also investigated\textsuperscript{592} the aromatic amination reaction with hydrazoic acid catalyzed by AlCl\textsubscript{3} or H\textsubscript{2}SO\textsubscript{4}, but the reaction conditions necessitate a 2:1 ratio of catalyst to azide at reflux temperature, giving only modest yields.

Olah and co-workers\textsuperscript{593} have carried out a comprehensive investigation of aminodiazonium ions under superacid conditions using \textsuperscript{13}C and \textsuperscript{15}N NMR spectroscopic methods (see Section 4.2.5.2). They also studied the electrophilic amination ability of these aminodiazonium ions. It has been found\textsuperscript{594,595} that NaN\textsubscript{3} (or trimethylsilyl azide) reacts with AlCl\textsubscript{3} and dry HCl in situ to form aminodiazonium tetrachloroaluminate \textsuperscript{145} [Eq. (5.211)], which reacts with a variety of arenes to give the corresponding aromatic amines [Eq. (5.212)]. Best results for aromatic aminations were obtained when an excess of the aromatic substrate itself was used as the reaction medium. The results are summarized in Table 5.33.

\begin{align*}

Subsequently they showed that trimethylsilylazide is an even more effective reagent when applied in the presence of triflic acid to afford the corresponding aminated products in high yields (73–95%, 40–70°C, 50–90 min). The suggested reaction pathway involves the formation of the aminodiazonium ion intermediate upon protonation with triflic acid, which then reacts with the arenes. This method has been successfully applied in the surface functionalization of polystyrene nanospheres (PS) with a loading of 0.19 mmol of amine group g⁻¹ [Eq. (5.213)].

\[
\text{PS} + \text{Me}_3\text{SiN}_3 \xrightleftharpoons[1,2\text{-dichlorobenzene, 55–60°C, 12 h}]{\text{CF}_3\text{SO}_3\text{H}} \rightarrow \text{PS} + \text{NH}_3^+ \text{TiO}^- 
\]

(5.213)

Triflic acid effectively promotes the phenylamination of aromatics with phenylazide in a fast, convenient, high-yield process (Table 5.34). The high ortho/para selectivity with only a small amount of meta product and high substrate selectivity \((k_T/k_B = 11)\) indicate the involvement of a substantially electron-deficient species, the phenylaminodiazonium ion intermediate with the possible protosolvation by triflic acid.

### 5.12. OXYFUNCTIONALIZATION

Converting alkanes and aromatics in a controlled way into their oxygenated compounds is of substantial interest. The discovery and development of superacidic...
systems and weakly nucleophilic solvent such as HSO$_3$F–SbF$_5$–SO$_2$, HSO$_3$F–SbF$_5$–SO$_2$ClF, and HF–SbF$_5$–SO$_2$ClF have enabled the preparation and study of a variety of carbocations (see Chapter 3). In connection with these studies, it was also found that electrophilic oxygenation of alkanes with ozone (O$_3$) and hydrogen peroxide (H$_2$O$_2$) takes place readily in the presence of superacids under typical electrophilic conditions. The reactions giving oxyfunctionalized products of alkanes can be explained as proceeding via initial electrophilic attack by protonated ozone HO$_3$+ or the hydrogen peroxonium ion H$_3$O$_2$+, respectively, on the σ-bond of alkanes through pentacoordinated carbonium ions.

In recent years, oxyfunctionalization of various natural products (steroids, alkaloids) under superacidic conditions have also been explored. In addition, Nafion resins in combination with various oxidizing agents have also been used in the oxygenations.

5.12.1. Oxygenation with Hydrogen Peroxide

5.12.1.1. Oxygenation of Alkanes

Hydrogen peroxide (H$_2$O$_2$) in superacidic media is protonated to hydrogen peroxonium ion (H$_3$O$_2$+) \[ \text{Eq. (5.214)} \]. Christe et al.\textsuperscript{600} have reported characterization and even isolation of several peroxonium salts. The $^{17}$O NMR spectrum of H$_3$O$_2$+ has also been obtained.\textsuperscript{601}

\[
\begin{align*}
\text{HOOH} & \xlongequal{H^+} \text{H}^+ \text{HOOH} \equiv [\text{OH} \cdot \text{H}_2\text{O}] \\
(5.214)
\end{align*}
\]

The hydrogen peroxonium ion may be considered as an incipient OH$^+$ ion capable of electrophilic hydroxylation of single (σ) bonds in alkanes and, thus, be able to effect reactions similar to such previously described electrophilic reactions as protolysis, alkylation, chlorination (chlorolysis), and nitration (nitrolysis).

The reaction of branched-chain alkanes with hydrogen peroxide in Magic Acid–SO$_2$ClF solution has been carried out with various ratios of alkane and hydrogen peroxide and at different temperatures.\textsuperscript{602} Some of the results are summarized in Table 5.35.

Because neither hydrogen peroxide nor Magic Acid–SO$_2$ClF alone led to any reaction under the conditions employed, the reaction must be considered to proceed via electrophilic hydroxylation. Protonated hydrogen peroxide inserts into the C–H bond of the alkane. A typical reaction path is as depicted in Scheme 5.60 for isobutane.

The reaction proceeds via a pentacoordinate hydroxycarbonium ion transition state, which cleaves to either tert-butyl alcohol or the tert-butyl cation. Since 1 mol of isobutane requires 2 mol of hydrogen peroxide to complete the reaction, one can conclude that the intermediate alcohol or carbocation reacts with excess hydrogen peroxide, giving tert-butyl hydroperoxide. The superacid-induced rearrangement and cleavage of the hydroperoxide results in very rapid formation of the dimethylmethyldimethylcarboxonium ion, which, upon hydrolysis, gives acetone and methyl alcohol.

When the reaction is carried out at room temperature, by means of passing isobutane into a solution of Magic Acid and excess hydrogen peroxide, the formation
of methyl alcohol, methyl acetate, and some dimethylmethylcarboxonium ion together with dimeric acetone peroxide was observed. These results clearly show that the products observed can be rationalized as arising from hydrolysis of the carboxonium ion and from Baeyer–Villiger oxidation of acetone.

The mechanism was substantiated by independent treatment of alkane hydroperoxides with Magic Acid.\textsuperscript{603} Similarly, Baeyer–Villiger oxidation of several ketones in the presence of H$_2$O$_2$ and superacids gave similar product compositions.

$^a$H NMR probe temperature.

$^b$DAP: dimeric acetone peroxide.

![Scheme 5.60]
Under the same reaction conditions as employed for branched-chain alkanes, straight-chain alkanes such as ethane, propane, butane, and even methane gave related products. Methane, when reacted with hydrogen peroxide–Magic Acid above 0°C, gave mainly methyl alcohol. A similar result was obtained with hydrogen peroxide–HSO$_3$F at 60°C. Ethane with hydrogen peroxide–Magic Acid at −40°C gave ethyl alcohol. The reaction of propane with hydrogen peroxide takes place more easily than that of methane or ethane and yields isopropyl alcohol as the initial oxidation product. On raising the temperature, isopropyl alcohol gave acetone, which underwent further oxidation with hydrogen peroxide, giving dimeric acetone peroxide, methyl acetate, methyl alcohol, and acetic acid.

The activation barriers for the hydroxylation of simple alkanes (methane, ethane, propane, butane, and isobutane) with the hydroperoxonium ion were calculated to be 5.26, 0.16, −4.64, −4.74, and −4.98 kcal mol$^{-1}$, respectively (MP4//MP2/6-31G** level). The same order of reactivity has been found at the B3LYP/6-31G(d,p) level (the corresponding activation barrier values for the hydroxylation of methane and ethane are 2.58 and 1.40 kcal mol$^{-1}$, respectively). Both studies showed that the high reactivity of the H$_3$O$_2^+$ ion originates from its relatively low LUMO energy (−9.18 eV). This value is approximately the same or even lower than the HOMO energy of alkanes (−10.8 to −8.0 eV). This facilitates a nucleophilic electron transfer of σ electrons to the σ* orbital of the peroxy bond. Reaction path calculations showed that the electrophilic oxygen atom of the hydroperoxonium ion attacks the hydrogen atom of the C−H bond. Consequently, dehydration takes place without the intervention of the pentacoordinate carbocation, and the carbenium ion formed is then hydrated to form protonated alcohol.

5.12.1.2. Oxygenation of Aromatics. Although there have been reports of the direct, one-step hydroxylation of aromatic compounds with peracids in the presence of acid catalysts, monohydroxylated products (i.e., phenols) have generally been obtained in only low yields. Although moderate-to-good yields of phenols, based on the amount of hydrogen peroxide used, were reported for the AlCl$_3$-catalyzed reaction of simple aromatics with hydrogen peroxide, a 10-fold excess of aromatics was used over hydrogen peroxide. The conversion of the aromatics thus was low, probably due to the fact that introduction of an OH group into the aromatic ring markedly increases its reactivity and thus tends to promote further side reactions. It is well-recognized that phenols are completely protonated in superacidic solutions. This raised the possibility that protonated phenols, once formed in these media, might resist further electrophilic attack. Electrophilic hydroxylations of aromatics with hydrogen peroxide (98%) in superacidic media has been achieved by Olah and Ohnishi in Magic Acid, which allows clean, high-yield preparation of monohydroxylated products. Benzene, alkylbenzenes, and halobenzenes are efficiently hydroxylated at low temperatures. The obtained yields and isomer distributions are shown in Table 5.36. Subsequently, Olah et al. found that benzene and...

Reactions were performed in HSO$_3$F–SO$_2$ClF solution at −78°C.

aBased on chromatographic analysis of quenched phenolic products. Parentheses show position of substituent(s).
bBased on aromatics used.

alkylbenzenes are smoothly hydroxylated using 30% H$_2$O$_2$ in HF–BF$_3$ acid system at low temperatures. The above method is particularly attractive because the acid system is recoverable and recyclable.

All these reactions involve hydroxylation of aromatics by hydrogen peroxonium ion [Eq. (5.215)].

\[
\begin{align*}
R & + \text{H}_3\text{O}^+ \rightarrow \text{H}_2\text{O} & \rightarrow \text{HO} & \rightarrow \text{H}^+ \\
& & \text{R} & \text{OH} & \text{OH} \\
& & & & (5.215)
\end{align*}
\]

Olah et al. have also hydroxylated naphthalene to the corresponding naphtols. Depending upon the acid strength of the medium employed, preferentially α- or β-naphthol is formed. In hydroxylation with 90% H$_2$O$_2$ in hydrogen fluoride or HF–solvent systems the actual electrophilic hydroxylating agent is the hydroperoxonium ion (H$_2$O$_2$\(^+\)), resulting in the formation of α-naphthol by the usual aromatic electrophilic substitution mechanism. In superacids (HF–BF$_3$, HF–SbF$_5$, HF–TaF$_5$, HSO$_3$F, HSO$_3$F–SbF$_5$), in contrast, β-naphthol is formed through the attack of hydrogen peroxide to protonated naphthalene according to Eq. (5.216).
Jacquesy and co-workers\textsuperscript{620} have developed a new route to resorcinols by reacting alkyl-substituted phenols or their ethers with H\(_2\)O\(_2\) in HF–SbF\(_5\). The products observed are formed by the reaction of H\(_3\)O\(^+\) either on neutral substrate or on the corresponding O-protonated ions. When the C-protonated form is highly stabilized by alkyl substituents, no hydroxylation occurs. Ring-substituted higher phenol ethers (R = Et, \(n\)-Pr) isomerize\textsuperscript{621} and are then hydroxylated to dialkyl resorcinol.\textsuperscript{622} Even hydroxylation of aromatic aldehydes and ketones in HF–SbF\(_5\) medium has been achieved with H\(_2\)O\(_2\).\textsuperscript{623} No Baeyer–Villiger oxidation products were detected in these reactions.

The H\(_2\)O\(_2\)–HF–SbF\(_5\) system has been applied by Jacquesy and co-workers in the hydroxylation of a variety of functionalized arenes.\textsuperscript{624} Hydroxylation of phenyl esters has been shown to afford the \textit{meta} and \textit{para} isomers as main products\textsuperscript{625} [Eq. (5.217)]. Substantial amounts of the deacylated derivatives were obtained in the reaction of phenyl formate and diphenyl carbonate. In the hydroxylation of 2-chlorophenyl and 4-chlorophenyl acetate, regioselectivity is controlled by the chlorine substituent with the hydroxyl entering into the \textit{meta} position to the ester group.\textsuperscript{626} A similar effect was observed in the hydroxylation of anilines and anilides.

\begin{equation}
\text{H}_2\text{O}_2 + \text{R} = \text{Me, MeO, Ph} \xrightarrow{\text{HF–SbF}_5} \text{R} = \text{Me, MeO, Ph, Ph} \text{O} = \text{C} = \text{O} \xrightarrow{\text{ortho, meta, para selectivity}} \text{2.5–23:30–64:30–52} \text{HO} \quad 83.5–98\% \text{ yield}
\end{equation}

The procedure has also been applied for the hydroxylation of aromatic amines. Aniline and its \(N\)-alkyl-substituted derivatives show similar behavior under similar conditions to afford the \textit{meta}-substituted aminophenols as the major hydroxylated product.\textsuperscript{627} Product formation was interpreted by the attack of protonated hydrogen peroxide on the anilinium ion protected by \(N\)-protonation from oxidation or degradation. Indoles, indolines, and tetrahydroquinoline have also been successfully hydroxylated with H\(_2\)O\(_2\) in HF–SbF\(_5\) with the hydroxyl group \textit{meta} to the nitrogen function.\textsuperscript{559,628} Hydroxylation of tryptophane and tryptamine derivatives affords pretonine and serotoninine derivatives in 42\% and 38\% yields, respectively.\textsuperscript{629}
It is noteworthy to point out that polyhydroxylation in most cases is practically suppressed under the reaction conditions because phenols are totally $O$-protonated in the superacid media and thus deactivated against further electrophilic attack or secondary oxidation. However, it has been shown by Jacquesy et al.\textsuperscript{630} that hydroxylation of $\alpha$- and $\beta$-naphthols can be achieved in $\mathrm{H}_2\mathrm{O}_2$--$\mathrm{HF}$--$\mathrm{SbF}_5$ under certain conditions. The hydroxylation occurs selectively on the nonphenolic ring.

5.12.1.3. Oxygenation of Natural Products\textsuperscript{631} Jacquesy and co-workers have also studied the hydroxylation of a series of natural products, including estrone and its acetate, and various alkaloids. Hydroxylation of vincadifformine in $\mathrm{HF}$--$\mathrm{SbF}_5$ with $\mathrm{H}_2\mathrm{O}_2$ (4 equiv., 0°C, 30 min) yields a mixture of two monohydroxylated derivatives in 60\% yields, whereas products with exclusive substitution at C(11) (146) are obtained in the reaction of 2,16-dihydrovincadifformine and its 14$\beta$-hydroxy analog.\textsuperscript{632} This corresponds to the same regioselectivity observed for indoles and indolines. A mixture of all four possible hydroxylated derivatives (147) were obtained in a combined yield of 69\% in the oxidation of yohimbine with $\mathrm{Na}_2\mathrm{SO}_5$ (HF--$\mathrm{SbF}_5$, $-35^\circ\mathrm{C}$, 1 h).\textsuperscript{633}

[Diagram of molecules]

Quinine acetate, 9-epiquinine, and 9-epiquinine acetate give mixtures of 10-keto (148) and 10-fluoro-3-hydroxy (149) derivatives upon treatment with $\mathrm{H}_2\mathrm{O}_2$ in HF--$\mathrm{SbF}_5$ (Scheme 5.61).\textsuperscript{634} Each product is epimeric at C(3). The initial isomerization (double bond migration) to form the exocyclic alkene 150 followed by the attack of electrophile “OH$^+$” equivalent to yield isomeric protonated epoxides 151 are the key steps in product formation [Eq. (5.218)]. Isomerization of epoxides affords the ketones and trans ring opening by $\mathrm{F}^-$ gives the fluorohydrins.
5.12.2. Oxygenation with Ozone

Ozone can be depicted as the resonance hybrid of canonical structures \(152a-152d\), and one might expect ozone to react as a 1,3-dipole, an electrophile, or a nucleophile. The electrophilic nature of ozone has been recognized in its reactions toward alkenes, alkynes, arenes, amines, sulfides, phosphines, and so on. Reactions of ozone as a nucleophile, however, are less well documented.

\[
\begin{align*}
\text{RO} & = (R)-\text{OAc} \quad 20 : 20 : 20 : 10 \\
\text{RO} & = (S)-\text{OH} \quad 6 : 6 : 16 : 8 \\
\text{RO} & = (S)-\text{OAc} \quad 15 : 15 : 33 : 17
\end{align*}
\]

Scheme 5.61

It was shown in the reaction of ozone with carbenium ions\(^{642}\) that the initial attack as expected is alkylation of ozone giving rise to intermediate trioxide, which then undergoes carbon to oxygen alkyl group migration with simultaneous cleavage of a molecule of oxygen, similar to the acid-catalyzed rearrangement of hydroperoxides to carboxonium ions (Hock reaction) [Eq. (5.219)].
When a stream of oxygen containing 15% ozone was passed through a solution of isobutane in HSO$_3$F–SbF$_5$–SO$_2$ClF solution held at $-78^\circ$C, the colorless solution immediately turned brown in color. $^1$H and $^{13}$C NMR spectra of the resultant solution were consistent with the formation of the dimethylmethylcarboxonium ion in 45% yield together with trace amounts of acetylium ion (CH$_3$CO$^+$). Further oxidation products (i.e., acetylium ion and CO$_2$) were reported to be observed in a number of reactions studied. Such secondary oxidation products, however, are not induced by ozone. Similar treatment of isopentane, 2,3-dimethylbutane, and 2,2,3-trimethylbutane resulted in formation of related carboxonium ions as the major products (Table 5.37).

For the reaction of ozone with alkanes under superacidic conditions, two mechanistic pathways could be considered. The first possible pathway is the formation of an

</table>
alkylcarbenium ion via protolysis of the alkane prior to quenching of the ion by ozone, as shown in Eq. (5.220). Alkylcarbenium ions may also be generated via initial oxidation of the alkane to an alcohol followed by protonation and ionization [Eq. (5.221)]. There have already been a number of reports of ozone reacting with alkanes to give alcohols and ketones. In both cases, intermediate alkylcarbenium ions would then undergo nucleophilic reaction with ozone as described earlier [Eq. (5.219)].

\[
\begin{align*}
R^1\text{C}^-\text{H} & \xrightarrow{\text{H}^+} \left[ R^1\text{C}^+\text{C}^-\text{H} \right]^+ \\

\end{align*}
\]

The products obtained from isobutane and isoalkanes (Table 5.37) are in accord with the above-discussed mechanism. However, the relative rate of formation of the dimethylmethylcarboxonium ion from isobutane is considerably faster than that of the tert-butyl cation from isobutane in the absence of ozone under the same conditions. Indeed, a solution of isobutane in excess Magic Acid–SO\textsubscript{2}Cl\textsubscript{2} solution showed only trace amounts of the tert-butyl cation after standing for 5 h at \(-78^\circ\text{C}\). Passage of a stream of oxygen gas through the solution for 10 times longer a period than in the ozonization experiment showed no effect. It was only when ozone was introduced into the system, that rapid reaction took place.

On the other hand, tert-butyl alcohol itself in Magic Acid–SO\textsubscript{2}Cl\textsubscript{2} solution gave the tert-butyl cation readily and quantitatively, even at \(-78^\circ\text{C}\). In the presence of ozone, however, under the same conditions it gave dimethylmethylcarboxonium ion.

Although isobutane does not give any oxidation products in the absence of Magic Acid under the same low-temperature ozonization conditions, it was not possible for the authors to determine whether formation of intermediate oxidation products, such as alcohols, plays any role in the ozonization of alkanes in Magic Acid. There is no experimental evidence for reactions proceeding via the intermediacy of carbenium ions; whether the initial oxidation step of alkanes to alcohols is important. This oxidation, indeed, was found to be extremely slow in the acidic media studied.

The most probable reaction path postulated for these reactions is electrophilic attack by protonated ozone [Eq. (5.222)] on alkanes, resulting in oxygen insertion into the involved \(\sigma\)-bond and cleavage of \(\text{H}_2\text{O}_2\) from pentacoordinated trioxide insertion transition state giving a highly reactive oxonium ion intermediate, which immediately rearranges to the corresponding carboxonium ion, which can be hydrolyzed to ketone and alcoholic products [Eq. (5.223)].
Since ozone is a strong 1,3-dipole, or at least has a strong polarizability (even if a singlet biradical structure is also feasible), it is expected to be readily protonated in superacids, in manner analogous to its alkylation by alkylcarbenium ions. Protonated ozone HO$_3^+$, once formed, should have a much higher affinity (i.e., be a more powerful electrophile) for $\sigma$-donor single bonds in alkanes than neutral ozone.

Attempts to directly observe protonated ozone by $^1$H NMR spectroscopy were inconclusive because of probable fast hydrogen exchange with the acid system (may be through diprotonated ozone H$_2$O$_3^+$) and also the difficulty in differentiating between shifts of HO$_3^+$ and H$_3$O$^+$. Straight-chain alkanes also efficiently react with ozone in Magic Acid at $-78^\circ$C in SO$_2$ClF solution. Ethane gave protonated acetaldehyde as the major reaction product together with some acetylium ion (Scheme 5.62). Reaction of methane, however, is rather complex and involves oxidative oligocondensation to tert-butyl cation, which reacts with ozone to give methylated acetone (Scheme 5.63).

Similar reactions have been investigated with a wide variety of alkanes. Cycloalkanes in particular give cyclic carboxonium ions along with protonated ketones. The reaction of cyclopentane is shown in Scheme 5.64.

Even electrophilic oxygenation of functionalized compounds has been achieved. Alcohols are oxidized to the corresponding keto-alcohols [Eq. (5.224)].
Ketones and aldehydes are oxidized to their corresponding dicarbonyl compounds [Eq. (5.225)].
In the case of carbonyl compounds, the C–H bond located farther than γ-position seems to react with ozone in the presence of Magic Acid. It appears that the strong electron-withdrawing effect of protonated carbonyl group is sufficient to inhibit reaction of these C–H bonds (in α-, β-, and γ-positions). Jacquesy and co-workers have shown that protonated ozone in HF–SbF$_5$ reacts with 3-keto-steroids bearing various substituents such as carbonyl, hydroxy, and acetox groups at the 17 positions. In situ diprotonation of the substrate in the superacid medium directs the electrophilic attack of ozone to the B- or C-ring methylenes. The position of oxidation depends both on the steric hindrance of the corresponding axial C–H bond and the remoteness of the positive charges initially present (diprotonated species) in the molecule. For example, 3,17-diketosteroids (R = O) only lead to the formation of the corresponding 3,6,17- and 3,7,17-triketones (153a and 153b, respectively, R = O) (Scheme 5.65), whereas oxidation at the 11 or 12 position is also observed when an OH or OAc group is present at the 17β position (153c, R = βOH and 153d, R = βOAc, respectively) (Scheme 5.65). In all cases, the 6-keto to 7-keto ratio appears to be higher for substrates having a cis A/B ring junction as compared with those with trans one. Low reactivity of the 11 position, especially for substrates with cis A/B ring junction, was observed. Oxidation of the tertiary carbon atoms, however, was not observed in any of these systems.

![Scheme 5.65](image)

**5.12.3. Oxygenation Induced by Nafion Resins**

Frusteri and co-workers have evaluated the activity of Nafion-based membranes in the oxidation of light alkanes. The membranes were prepared by depositing a
carbon–Teflon paste on carbon paper followed by activation and subsequent impreg-
nation by a Nafion-H solution in isopropyl alcohol. They were evaluated in a three-way
catalytic reactor using Fe$^{2+}$–H$_2$O$_2$ as the oxidant. Of various acidic catalysts studied,
Nafion-H proved to be the best catalyst to afford the selective oxidation of methane (to
methanol), ethane (ethanol and acetaldehyde), and propane (1- and 2-propanol,
propanal, acetone) under mild conditions ($80–110^\circ$C, 1.4 bar). The high efficiency
of Nafion-H was attributed to its high chemical stability toward H$_2$O$_2$.

Nafion-H is an effective catalyst in the Baeyer–Villiger oxidation of cyclic and
polycyclic ketones to form lactones in high yields (86–100%) with H$_2$O$_2$ or meta-
chlorobenzoic acid in refluxing dichloromethane.\(^6\) Nonsymmetric ketones, such as
2-methylcyclopentanone, give isomeric mixtures depending on the migratory aptitude
of the group adjacent to the carbonyl function [Eq. (5.226)].

\[
\begin{align*}

\text{86\% yield} & \\
\end{align*}
\]

(5.226)

When Nafion SAC-13 and SAC-40 were used in the Baeyer–Villiger oxidation
of cyclopentanone, the peroxidic byproduct dicyclopentylidenediperoxide \(^{154}\) was obtained with unusually high selectivity (24\% yield)\(^{653}\) [Eq. (5.227)]. This
was interpreted in terms of the high acid strength of Nafion leading to the preferable
formation of H$_3$O$_2^+$ species able to form the peroxidic byproduct. Nafion NR50
has been found to be an efficient and recyclable catalyst in the oxidation of
various organic compounds with 30\% H$_2$O$_2$ under mild conditions.\(^6\) High yields
were achieved in the oxidation of secondary alcohols to esters or lactones,
aldehydes in methanol to methyl esters, tertiary amines to N-oxides, and sulfides
to sulfoxides.

\text{24\% yield} & \\
\end{align*}
\]

(5.227)

A clean, solvent-free method has been developed for the bis-hydroxylation of
alkenes by the use of Nafion-based acidic catalysts and 30\% H$_2$O$_2$.\(^6\) Nafion NR50
and SAC-13 exhibited high activity in the oxidation of isomeric C$_6$ alkenes, cyclo-
hexene [Eq. (5.228)], 1,4-cyclohexadiene, and allylic alcohols in the temperature
range of 70–90°C to afford the corresponding 1,2-diols in moderate to excellent yields (40–100%).

\]

Hoelderich and co-workers\textsuperscript{656,657} have applied various acidic resins loaded with Pt and Pd to perform direct hydroxylation of benzene to produce phenol. Among various Nafion SAC catalysts (loadings between 8 and 80%), SAC-13 gave the best results. The highest phenol yield of 7.6% was found using a semicontinuous process over a pre-reduced catalyst (0.5 wt% Pd + 0.5 wt% Pt/SAC-13, 30–40°C, 1.3 L h\(^{-1}\) H\(_2\) and O\(_2\) flow, and 1.4 L h\(^{-1}\) N\(_2\) flow, 1400 kPa, water–methanol solvent).

Ohsaka and co-workers\textsuperscript{658} have reported a new method to prepare peroxycetic acid by oxidizing acetic acid with H\(_2\)O\(_2\) in the presence of Nafion catalysts. Nafion-H proved to be superior to Nafion SAC-13 to give a conversion of 16% (5% of catalyst, initial reactant concentrations: [CH\(_3\)COOH] = 1.65 M, [H\(_2\)O\(_2\)] = 2.85 M, 17 h).

### 5.12.4. Oxygenation by Other Methods

The CCl\(_4\)–HF–SbF\(_5\) system developed by Jouannetaud and co-workers and used in the selective fluorination of imines (see Section 5.10.1) can be applied in the oxygenation of ketones and carboxamides as well. The hydroxylation of ketones is selective [Eq. (5.229)], provided that a five- or six-membered cyclic carboxonium ion preventing fluorination is involved.\textsuperscript{534,659} Fluorination, however, may be a side reaction with product distributions depending on quenching conditions (aqueous Na\(_2\)CO\(_3\) or HF–pyridine). Similar features are characteristic of the transformation of carboxamides.\textsuperscript{659}

\]

Karpov and co-workers developed two methods to transform perfluorinated cyclic compounds to the corresponding oxo-derivatives. When perfluoroindane (155) is treated in the presence of SiO\(_2\) and SbF\(_5\), perfluoroindan-1-one is formed in high yield\textsuperscript{660} [Eq. (5.230)]. According to the suggested mechanism, SiO\(_2\) serves as the oxygen source by reacting with the carbocation intermediate formed by F\(^–\) loss. The selectivity of oxygenation is highly sensitive to the reaction conditions since the
product is prone to undergo complex transformations. Perfluorinated benzocyclobutene, indane and their perfluoroalkyl-substituted derivatives (156) [Eq. (5.231)], and perfluoroalkylbenzenes are transformed in CF$_3$COOH–SbF$_5$ to give carbonyl derivatives under mild conditions in high yields. The key step in product formation, in this case, is the acyloxylation of the carbocation intermediate by CF$_3$COOH.

Bis(trimethylsilyl) peroxide$^{662}$ and sodium perborate$^{663}$ are also efficient electrophilic oxygenating agents in the presence of triflic acid. Both reagents are capable of the selective monohydroxylation of aromatics to the corresponding phenols in high yields [Eq. (5.232)]. Isomer distributions are in accordance with the electronic nature of the reactions. Moderate substrate selectivity ($k_T/k_B = 20$) was found with bis (trimethylsilyl)peroxide in the competitive hydroxylation of benzene and toluene at $-40^\circ$C. The byproduct (trimethylsilyloxy)arenes support a mechanistic pathway with the involvement of (trimethylsilyloxy)arenium ions. Bis(trimethylsilyl) peroxide was also used in the hydroxylation of polystyrene nanospheres promoted by triflic acid.$^{597}$

Adamantane can be transformed to 4-oxahomoadamantane in good yields by bis(trimethylsilyl)peroxide and sodium percarbonate in the presence of triflic acid. Product formation is explained by C–C σ-bond insertion [Eq. (5.233)]. Diamantane is transformed into isomeric oxahomodiamantanes (C–C insertion) and bridgehead diamantanols (C–H insertion).

5.13. SUPERACIDS IN PROTECTION GROUP CHEMISTRY

Olah et al. have developed a highly efficient thioacetalization method using boron trifluoride monohydrate BF$_3$–H$_2$O. A variety of carbonyl compounds, aromatic and aliphatic aldehydes, and ketones were readily transformed to the corresponding 1,3-dithiolanes in high yields (90–99%) under mild conditions (CH$_2$Cl$_2$ solution, 0°C, 15–30 min). A new method for the synthesis of stannyl ethers for further use in glycosylation has been reported by Yamago, Yoshida, and co-workers [Eq. (5.234)]. The efficiency of the method applicable for primary and secondary alcohols was tested by benzoylation.

\[

\]

A newly developed stable dimethyl ether–HF complex (1:15), which can be stored at room temperature, is highly effective for the deprotection and cleavage of peptides from Merrifield resins (isolated peptide yields = 88–94%). It can easily be handled, and it is a very useful and convenient hydrogen fluoride equivalent.

Amorphous and mesostructured ZrO$_2$ solid catalysts loaded with various amounts of triflic acid (5–30%) were tested in the acetalization of ethyl acetoacetate to form fructone [Eq. (5.235)]. Whereas the amorphous samples [ZrO$_2$(a)–TfOH] were nonselective and induced the formation of a byproduct, the mesoporous catalysts [ZrO$_2$(m)–TfOH] showed complete selectivity to give the desired product in high yields.
Fluoroboric acid supported on silica (HBF₄–silica) has recently been found to be a highly efficient catalyst in the protection of various functional groups. Structurally diverse alcohols, phenols, thiophenols, and anilines can be acylated under solvent-free conditions at room temperature.¹⁶⁹ Even acid-sensitive tertiary alcohols (1-alkylcyclohexanols) and sterically hindered compounds, such as endo-borneol, give the acylated products in high yields. A triflic acid–silica catalyst also shows high activity in the O-acetylation with Ac₂O of alcohols and phenols.³⁵⁹

The transformation of carbonyl compounds to O,S-acetals and S,S-acetals can be carried out without solvent under mild conditions (1 mol% of catalyst, room temperature, 5–40 min) to afford the products in high yields (70–97%).¹⁶⁷ O,O- and O,S-acetals are also readily transformed to S,S-acetals [Eq. (5.236)].

\[
\begin{align*}
  R &= C_9H_{19}, \text{Ph, 4-MeC}_6H_4, 4-\text{HOCC}_6H_4, \\
  &\quad 4-\text{ClC}_6H_4, 4-\text{MeOC}_6H_4, 4-\text{NO}_2C_6H_4, \\
  &\quad 4-\text{BrOC}_6H_4, \text{PhCH}_2\text{CH}_2, \text{PhCH}=\text{CH} \\
  R' &= \text{H, Me} \\
  X &= (\text{OMe})_2, (\text{OEt})_2, \text{O(CH}_2)_n\text{O, O(CH}_2)_n\text{S} \\
  n &= 1, 2
\end{align*}
\]

HBF₄–silica also exhibits high activity in the protection of aldehydes as 1,1-diacetates (acylals)¹⁶¹ [Eq. (5.237), Table 5.38]. Both aliphatic and aromatic aldehydes react readily to form diacetates in high yields. The catalyst can be reused with marginal decrease in activity.

\[
\begin{align*}
  R \quad &\text{H} \quad \text{Ac} \\
  &\text{C} \\
  &\text{O} \\
  &\text{H} \\
  &\text{OAc} \\
  &\text{OAc}
\end{align*}
\]

Nafion-H has been shown to be effective in a variety of protection–deprotection reactions including O-trialkylsilylation of alcohols, phenols, and carboxylic acids, as well as the preparation and methanolation of tetrahydropyranyl (THP) ethers.¹⁶² However, when compared, for example, with HBF₄–silica or Nafion nanocomposites,
Nafion-H exhibits lower activity. In the acetylation of alcohols, in the transformation of aldehydes and ketones with trimethyl orthoformate to the corresponding dimethylacetals, and in the formation of acylals, longer reaction times (several hours) are required to achieve high yields at room temperature. Furthermore, the formation of ethylenedithioacetals in benzene and the direct transformation of acetals to thiaacetals with ethane-1,2-thiol in dichloromethane can only be performed at reflux temperature.

The catalytic performance of Nafion SAC-13 in the formation of 1,1-diacetates, in turn, is very similar to that of HBF$_4$-silica. In the acetalization of carbonyl compounds with ethane-1,2-diol and propane-1,3-diol, products are isolated in good to excellent yields. The formation of THP ethers of alcohols is fast and protected alcohols are isolated in high yields [Eq. (5.238)]. Nafion SAC-13 can also be used in the removal of the THP ether group although the transformation requires somewhat longer reaction times (30 min–6 h, 81–97% yield). Furthermore, the catalyst could be recycled in all three processes with practically no loss of activity.

\[
\text{R OH} + \text{O} \xrightarrow{\text{Nafion SAC-13}} \text{ROO} \quad \text{CH}_2\text{Cl}_2, \text{RT, 30 min}
\]

\[
R = \text{isoBu, 1-C}_9\text{H}_{17}, 2-\text{C}_9\text{H}_{17}, \text{Bn, CH}_2=\text{CHCH}_2, \text{cycloC}_5\text{H}_9, \text{cycloC}_6\text{H}_{11}
\]

Nafion SAC-13 was also demonstrated to be a superior catalyst in the formation of mixed acetals in the reaction of alcohols with dialkoxy methanes [Eq. (5.239)].

Reaction conditions: aldehyde:Ac$_2$O = 1, 0.1 mol% of catalyst, room temperature.
product acetals are isolated in good to excellent yields in an almost instantaneous transformation and the catalyst can be reused with minor loss of activity.

\[
R\text{--OH} + (RO)_2CH_2 \xrightarrow{\text{Nafion SAC-13}} RO\text{--CH}_2\text{--OR}' \quad \text{CH}_2\text{Cl}_2, \text{reflux, } 5 \text{ min} \quad \text{83--100\%} \quad (5.239)
\]

R = 1-C$_8$H$_{17}$, 2-C$_8$H$_{17}$, Bn, PhCH$_2$CH$_2$, cycloC$_6$H$_{11}$, cholesteryl
R' = isoPr, Bu

Again, the activity of Nafion-H in the above protection processes (transformation of alcohols to THP ethers and methoxymethyl ethers) is lower, and consequently, longer reaction times and elevated temperatures are required to achieve yields comparable to those over Nafion nanocomposites. Obviously, this is due to the low specific surface area and low accessibility of the active sites of Nafion-H as compared with Nafion SAC-13.

A simple process for the trimethylsilylation of alcohols, phenols, and carboxylic acids in refluxing CH$_2$Cl$_2$ over Nafion-H has been reported by Olah et al. [Eq. (5.240)]. The transformation of phenols and carboxylic acids requires higher temperature (CCl$_4$ reflux).

\[
R\text{--OH} + \text{CH}_2=\text{CHCH}_2\text{SiMe}_3 \xrightarrow{\text{Nafion-H}} R\text{--O--SiMe}_3 \quad \text{CH}_2\text{Cl}_2 \text{or CCl}_4, \text{reflux, } 1--3.5 \text{ h} \quad \text{89--98\%} \quad (5.240)
\]

R = 1-C$_7$H$_{15}$, 2-C$_9$H$_{19}$, Bn, cycloC$_6$H$_{11}$, cycloC$_6$H$_{11}$CH$_2$, Ph, 2,6-diMeC$_6$H$_3$, C$_5$H$_{11}$CO, C$_6$H$_5$CO

Selective deprotection of trialkylsilyl ethers can also be accomplished by Nafion-H. Trimethylsilyl ethers are cleaved to the corresponding alcohols under mild conditions [Eq. (5.241)]. Nafion-H with NaI (1 equiv.) in methanol was shown to readily cleave tert-butyl dimethylsilyl ethers (room temperature, 4--25 h, 65--99% yields).

\[
R\text{CH}_2\text{--O--SiMe}_3 \xrightarrow{\text{Nafion-H}} R\text{--OH} \quad \text{hexane, RT, } 15--45 \text{ min} \quad \text{90--98\%} \quad (5.241)
\]

R = C$_6$H$_{13}$, C$_7$H$_{15}$, cyclo-C$_6$H$_{11}$, cycloC$_7$H$_{13}$, substituted Ph, PhCH=CH, PhCHMe, 1-indany, 2-thienyl

Nafion-H has also been applied in the transformation of protected organic compounds. Acetals and ketals can be reductively cleaved very efficiently to the
corresponding ethers with triethylsilane (CH\(_2\)Cl\(_2\) reflux, 1–4 h, 82–99% yields).\(^{682}\) The combination of acetal synthesis with the use of trimethyl orthoformate,\(^{674}\) and this cleavage method allows the one-pot direct conversion of carbonyl compounds to their alkyl ethers. Recently, Nafion-H has been applied in the conversion of primary and secondary trimethylsilyl ethers to the corresponding symmetric ethers\(^{683}\) (hexane, RT, 70–90% yield).

Hydroxamic acids protected in the form of dioxazoles can be readily recovered by treatment with Nafion-H in isopropyl alcohol\(^{684}\) [Eq. (5.242)]. The method is applicable to primary, secondary, tertiary, and aromatic hydroxamic acids and the byproduct isopropyl esters are formed only in negligible amounts (0–4%).

\[
\text{HO} + \text{MeCHOH} \xrightarrow{\text{Nafion-H reflux}} \text{R} - \text{C} = \text{N}\text{OH} \quad (5.242)
\]

Protection groups related to carbohydrate chemistry are discussed in Section 5.16.

### 5.14. SUPERACIDS IN HETEROCYCLIC CHEMISTRY

##### 5.14.1.1. Preparation of Oxacycloalkanes

Unsaturated alcohols can be cyclized under superacid conditions to yield oxolane derivatives. Laali et al.\(^{685}\) have studied the protonation of homoallylic adamantylideneadamantyl alcohols. The pseudo-axial alcohol 157 was protonated in HSO\(_3\)F–SO\(_2\)ClF to give the intermediate protonated cyclic ether observed by \(^1\)H and \(^13\)C NMR spectroscopy, which, upon quenching, furnished the corresponding ether [Eq. (5.243)].

\[
\begin{align*}
\text{HO} &\quad \text{1. HSO}_3\text{F–SO}_2\text{ClF, } -78^\circ\text{C} \\
\text{157} &\quad \text{2. quench} \\
\end{align*}
\]

(5.243)
Derivatives with five- and six-membered oxygen-containing rings have been isolated when vindoline and deacetylvindoline were treated under superacid conditions. Formation of the unexpected oxolane derivatives (R = Ac: 4%, R = H: 18%) was accounted for by rearrangement through ethyl and hydride shifts (Scheme 5.66).

The ring-closure (cyclodehydration) of dihydroxy compounds affords five-, six-, seven-, and eight-membered cyclic ethers. The reaction can efficiently and conveniently be carried out with Nafion-H. Even diphenols (2,2'-dihydroxybiphenyls) undergo dehydration to afford oxolane derivatives [Eq. (5.244)]. The low yields of the tert-butyl-substituted compounds result from trans-tert-butylation (see Section 5.2.6). Cyclodehydration of stereoisomeric 2,5-hexanediols was shown to be stereospecific: The racemic mixture yields cis-2,5-dimethyloxolane, whereas the meso diol gives the trans compound. This indicates that the transformation is an intramolecular S_N2 process without the involvement of carbocationic intermediates.
cis-2,6-Disubstituted 4-methylenetetrahydropyrans found in a variety of natural products can be synthesized by the highly diastereoselective (de > 98%) ring closure of enol ethers developed by Schrock, Hoveyda, and co-workers\cite{689} [Eq. (5.245)]. The use of triflic acid in very low amounts (0.01–0.1 mol%) is necessary to avoid polymerization.

Triflic acid supported on titania has proved to be an effective catalyst to transform hydroxyphenyl-1,3-propanediones to chromone derivatives in high yield and with high selectivity\cite{690} [Eq. (5.246)].

Nafion–silica nanocomposites exhibit high selectivity in the synthesis of substituted 7-hydroxychromanones 158 in high yields\cite{691} [Eq. (5.247)]. Conversions increase with increasing Nafion loading and, consequently, Nafion SAC-80 (Nafion–silica with a Nafion content of 80 wt%) affords the highest yields. The catalysts could be recycled after treatment with nitric acid or hydrogen peroxide.
A low amount (1 mol%) of triflic acid is sufficient to carry out the hetero Diels–Alder reaction of aromatic aldehydes with simple dienes to furnish 3,6-dihydro-2H-pyran derivatives in moderate to good yields\(^{692}\) [Eq. (5.248)]. The strongly deactivated \textit{para}-methoxybenzaldehyde and pentanal gave the products in very low yields.

3-Alkenamides react with trioxane in triflic acid to yield 3,6-dihydro-2\(H\)-pyran derivatives\(^{693}\) [Eq. (5.249)]. An oxo–ene reaction to form a homoallyl alcohol followed by a second oxo–ene reaction and subsequent dehydration were suggested to explain the product formation. Interestingly, lactam formation was not observed.
The 2,6-\textit{cis} isomers are formed exclusively and in all cases the equatorial C(4) epimer \textbf{159a} is the major product.

\[
\text{Me} \quad \text{OH} \quad + \quad \text{RCHO} \quad \xrightarrow{\text{CF}_3\text{SO}_3\text{H}} \quad \text{Me} \quad \text{OH} \quad \overset{\text{Ph}}{\text{COMe}} \\
\text{Ph} \quad \text{OH} \quad \overset{\text{R = Me, isoPr, tert-Bu, Ph, PhCH}_2, \text{PhCH}_2\text{CH}_2, \text{PhCH}==\text{CH}}{=} \quad \overset{\text{nitromethane, } -25^\circ\text{C}, \ 2 \text{ h}}{\uparrow} \quad \text{Ph} \quad \overset{\text{COMe}}{\text{O}} \\
\overset{\text{159a/159b}}{\text{yields of 159a}} \quad 18:1-6:1 \quad \overset{\text{yields of 159a}}{=} \quad 61-81\% \quad \(5.250\)
\]

Nafion–silica nanocomposites (5\%, 13\%, 20\%, 40\%, and 80\% loading) have been applied in the synthesis of \(\alpha\)-tocopherol (\textbf{160}) in various solvents\cite{695,696} [Eq. (5.251)]. Under optimized conditions, Nafion SAC-40 proved to be the best catalyst (91\% yield of \(\alpha\)-tocopherol using 0.6 wt\% of catalyst). Catalyst recycling was possible after reactivation with oxidizing agents (nitric acid or hydrogen peroxide).

\[
\overset{\text{HO}}{\text{Nafion–silica}} \quad \overset{\text{toluene, reflux, 2 h or propylene carbonate–heptane, 100^\circ\text{C}, 1 h}}{\downarrow} \quad \overset{\text{H}_2\text{O}}{\text{160}} \quad (5.251)
\]

Bright, Coxon, and Steel\cite{697} reported the cyclization of a methallyl carbinol in HSO\textsubscript{3}F via the intermediacy of a protonated oxetane involving a unique oxygen atom migration [Eq. (5.252)].
Additional examples for the formation of oxacycloalkanes under superacidic conditions are to be found in Section 5.17.1.

5.14.1.2. Synthesis of Nitrogen Heterocycles. Pyrrolidines and piperidines are synthesized by intramolecular hydroamination of N-protected alkenylamines. Both triflic acid and conc. sulfuric acid are active; however, triflic acid gives better yields at much shorter reaction times [Eq. (5.253)]. 4-(para-Nitrophenyl)but-3-enylamine was unreactive, whereas the para-methoxy-substituted compound decomposed. The transformation of the tosylate of 1-isobutyl-pent-4-enylamine gave the 2,5-disubstituted pyrrolidine with modest selectivity (trans/cis = 68:32) The possible reaction pathway includes an intramolecular proton transfer from the protonated protected amino group to the double bond followed by trapping of the formed carbocation by the sulfonamide function.

The tandem cyclopropyl ring-opening/nitrilium ring-closing reaction in the presence of triflic acid results in the stereoselective formation of cyclic imines \( \text{161} \) (Scheme 5.67). Cyclic imines are obtained in the related transformation of methylenecyclopropanes with nitriles mediated by triflic acid \( \text{700} \) (Scheme 5.68). The reaction pathway suggested to interpret product formation is similar to that in Scheme 5.67. The reaction of intermediate \( \text{162} \) with water may give Ritter products (carboxamides) isolated in some cases.

Similar carbocationic intermediates may be involved in the transformation of substituted ethyl pentadienoates under Ritter conditions in excess triflic acid (3 equiv.) to furnish the bicyclic aza compounds \( \text{163} \) [Eq. (5.254)].
Scheme 5.67

Scheme 5.68

(5.254)
Dihydroquinoline derivatives are synthesized in intramolecular hetero Diels–Alder reaction from \( \alpha \)-(alkynylsiloxy)aldimines in triflic acid\(^7\) \[\text{Eq. (5.255)}\].

Efficient synthetic methods have been developed for the synthesis of 4-functionalized quinolines mediated by triflic acid.\(^8\) Electron-rich, highly reactive ethynyl ketene-\(S,S\)-acetals react readily with arylamines and aldehydes in an aza-Diels–Alder reaction to afford the desired products \[\text{Eq. (5.256)}\]. Arylimines and ethynyl ketene-\(S,S\)-acetals react similarly (60–70\% yields).

Knorr cyclization of a range of \(N\)-substituted butyramides in triflic acid yields 4-methyl-1\(H\)-quinolin-2-one derivatives\(^9\) \[\text{Eq. (5.257)}\]. Suggested intermediates of the transformation directly observed by low-temperature multinuclear NMR spectroscopy (\(\text{HSO}_3\text{F}\! -\! \text{SbF}_5\! -\! \text{SO}_2\text{ClF}, -40\text{°C}\)) are distonic superelectrophiles formed by diprotonation of the two carbonyl oxygen atoms.
When aliphatic azido compounds with a suitably placed alkene or alcohol function are treated with triflic acid, nitrogen heterocycles are formed. This intramolecular version of the Schmidt reaction affords the synthesis of 2-substituted pyrrolines from 4-substituted-3-butenyl azides, whereas fused or bridged aza compounds are obtained from exomethylene cycloalkanes or cycloalkene derivatives. The precondition for the reactions is the formation of stable (tertiary, allylic, benzylic, propargylic) carbocations, which are captured by the azido group followed by rearrangement to yield the final product after quenching. Azidoalkyl-substituted ketals or enol ethers of cycloalkanones also react under similar conditions to form bicyclic lactams.
Vankar and co-workers\textsuperscript{709} have shown that Nafion-H can catalyze the hetero Diels–Alder reaction between the Danisefsky diene 164 and aromatic imines to form 2,3-dihydro-γ-pyridones (Scheme 5.69). The reaction with aromatic aldehydes, however, yields only the Mukaiyama aldol condensation products.

In analogy with the ring closure of 2,2\textsubscript{0}-dihydroxybiphenyls [Eq. (5.244)], Nafion-H catalyzes the formation of carbazole derivatives from 2,2\textsubscript{0}-diaminobiphenyls.\textsuperscript{710} The synthesis, however, requires higher temperature and 4-\textit{tert}-butyl-\textit{ortho}-xylene was found to be the best solvent [Eq. (5.260)].

\begin{equation}
\text{Scheme 5.69}
\end{equation}

\textbf{5.14.1.3. Heterocycles with Two or Three Heteroatoms.} As already discussed (see Sections 5.10.1 and 5.12.1.3), Jacquesy and co-workers\textsuperscript{548,549,634,711} have studied the transformations of various alkaloids in superacids. They have found that quinine and quinidine, but not epiquinine and epiquinidine, afford cyclization products resulting from the reaction between the 9-OH group and the rearranged quinuclidine skeleton (HF–SbF\textsubscript{5} or H\textsubscript{2}O\textsubscript{2}–HF–SbF\textsubscript{5}). The transformation illustrated by the reaction of quinine in Scheme 5.70 involves polyprotonated quinine, which undergoes a series of rearrangements before the final ring-closing step to yield the oxazapolycyclic product.

\begin{equation}
\text{(5.260)}
\end{equation}
Austin and Ridd\textsuperscript{712} have described an interesting ring-closing transformation of 1-ethyl-2-nitrobenzene to 3-methylbenzo[c]isoxazole in triflic acid. On the basis of deuterium labeling and the large substituent effect observed (the reaction of 1-methyl-2-nitrobenzene is extremely slow), the mechanism shown in Eq. (5.261) including a hydride transfer from the benzyl carbon to one of the oxygens of the protonated nitro group as the rate-determining step has been proposed.

Shudo and co-workers\textsuperscript{183} found that nitroalkenes react with benzene in triflic acid to yield 4\textit{H}-1,2-benzoazoles in a two-step reaction: the \textit{O,\textit{O}}-diprotonated
nitroalkene alkylates benzene (see Section 5.2.1) and then the diprotonated oxime intermediate undergoes ring closure to afford 4H-1,2-benzoxazines. A detailed study carried out recently by Ohwada and co-workers\(^{713}\) has shown that triflic acid in large excess (10 equiv.) can induce a similar intramolecular cyclization of methyl 3-aryl-2-nitropropionates to form 4H-1,2-benzoxazines [Eq. (5.262)]. Compounds with electron-donating substituents (para-methyl- and para-methoxyphenyl derivatives) and 3-naphthyl- and 3-indolyl-2-nitropropionates are either unreactive or give products in very low yields. The use of triflic acid–TFA mixtures showed that the transformation is highly sensitive to acid strength: An acidity of \(H_0 = -9.1\) (TfOH/TFA = 9:1) is required, which was interpreted in terms of activation by protonation of the methyl ester group.

\[
\begin{align*}
\text{R} = & \text{H, 3-Cl, 3-NO}_2, 4-F, 4-Cl, \\
& 4-Br, 4-CF_3, 4-NO_2, 4-NC
\end{align*}
\]

\(\text{CHCl}_3, 50^\circ\text{C}, 30 \text{ min} \quad \text{74-93\% yield} \quad (5.262)\)

\(\text{meta}\)-Substituted derivatives give isomeric products, whereas \(\text{ortho}\)-halogen-substituted compounds yield products formed via halogen shift [Eq. (5.263)]. It was also found that the ring-closing is characteristic of only 3-aryl-2-nitropropionates (formation of six-membered ring), whereas analogous compounds with longer alkyl chain (methyl phenyl-nitro-acetate, -butanoate, and -pentanoate) decomposed under identical reaction conditions.

\[
\begin{align*}
X, X' = & F: 10 \text{ equiv. of acid, } 30 \text{ min} \\
X = & H, X' = Cl: 50 \text{ equiv. of acid, } 1.5 \text{ h} \\

X, X' = & Br \quad 68
\end{align*}
\]

(5.263)

Deuterium labeling studies indicated that the electrocyclization mechanism necessitating the removal of a benzylic hydrogen, suggested earlier by Shudo and co-workers,\(^{183}\) is not operative here. Instead, experimental observations indicate the
involvement of the superelectrophilic diprotonated intermediate 165 stabilized by an intramolecular hydrogen bond (Scheme 5.71). Indeed, theoretical calculations showed that the activation energy of transition state 166 is significantly reduced compared to those of monocations (28.7 kcal mol$^{-1}$ versus 46.2 and 47.4 kcal mol$^{-1}$).

The transformation of optically active epoxides with acetonitrile into optically active oxazolines (167, 168) can be induced by various superacids$^{714}$ [Eq. (5.264)]. The reaction proceeds with inversion of the asymmetric center with high stereospecificity with anhydrous HF and AlCl$_3$, whereas partial racemization is observed in triflic acid (Table 5.39).

$^{a}$Enantiomeric excess.
A one-step synthesis of tricyclic diazadihydroacenaphthylenes with an isoxazoline ring has been developed from 1-benzylamino-1-methylthio-2-nitroethene derivatives induced by a large excess of triflic acid\textsuperscript{715} [Eq. (5.265)]. Dications 169, similar to those detected by Coustard,\textsuperscript{197} were observed by NMR spectroscopy. Quenching with water gives a reactive intermediate nitrile oxide, which undergoes an intramolecular cyclization to furnish the final products in fair yields.

An unusual oxetane cyclization of compound 170 with the participation of the neighboring carbonyl group to yield bicyclic acetal 171 can be induced by triflic acid\textsuperscript{716} [Eq. (5.266)].

1,3-Dioxanes can be efficiently synthesized from styrenes using formalin as the formaldehyde source (Prins reaction) with triflic acid as catalyst\textsuperscript{717} [Eq. (5.267)].
Superacids have been found to be efficient catalysts for the three-component condensation of aldehydes with 1,3-dicarbonyl compounds and urea (thiourea) to synthesize dihydropyrimidin-2(1H)-one derivatives (Biginelli reaction). Compared to the traditional process, the use of superacids results in high yields in shorter reaction times. Fluoroboric acid\(^\text{718}\) [Eq. (5.268)] and Nafion NR50 (acetonitrile, reflux, 74–96\%)\(^\text{719}\) have been shown to give excellent results even with aliphatic aldehydes. The use of cyclic 1,3-diketones allows the synthesis of octahydroquinazolinone derivatives in good yields\(^\text{720}\) [Eq. (5.269)]. Unexpectedly, 3- and 4-pyridincarboxaldehydes afforded hexahydroxanthenes.

\[
\begin{align*}

\]

45–94%

(5.267)

Nafion-H is highly efficient to induce the one-pot, three-component synthesis of 2,3-disubstituted 4-(3\(H\))-quinazolines under solvent-free conditions with microwave
irradiation\textsuperscript{721} [Eq. (5.270)]. Reactions are complete in a few minutes to afford the products in high yields.

\[
\text{Condensation–cyclization of fluoromethyl ketones with bifunctional aniline derivatives or anthranilic acid gives a range of fluorinated heterocycles (benzimidazoles, benzothiazolines, benzoxazolines and dihydrobenzoxazinones) over Nafion-H and Nafion SAC-13 both exhibiting high catalytic activity.}\textsuperscript{722} \text{Products are formed under mild conditions in high yields with high selectivity and purity. Illustrative is the transformation shown in Eq. (5.271).}
\]

\[
\text{Fluoroboric acid supported on silica is also highly efficient for the synthesis of 1,5-benzodiazepines under solvent-free conditions}\textsuperscript{723} \text{[Eq. (5.272)].}
\]
5.14.2. Ring Opening of Oxygen Heterocycles

Olah et al. have shown that Nafion-H induces the ring opening of oxiranes under mild conditions to afford various products. Substituted oxiranes undergo hydrolysis or alcoholdysis to yield 1,2-diols or 1,2-diol monoethers, when treated with Nafion-H under mild conditions in the presence of water or alcohols, respectively. Cycloalkene oxides give the corresponding trans products stereoselectively [Eq. (5.273)].

\[
\text{CH}_3(\text{CH}_2)_7(\text{CH}_2)_7\text{COOMe} + R-\text{OH} \xrightarrow{\text{Nafion-H}} \text{CH}_3(\text{CH}_2)_7(\text{CH}_2)_7\text{COOMe} \quad \text{(5.273)}
\]

Ring opening of epoxidized fatty esters with alcohols has been studied to explore the synthesis of vicinal hydroxy ethers, which are potential lubricants [Eq. (5.274)]. In a comparative study of ring-opening with methanol, Nafion SAC-13 showed superior activity (TOF = 1 min\(^{-1}\) versus 0.04 min\(^{-1}\) after 0.5 h at 60°C) when compared to Amberlist 15 (TOF = 0.04 min\(^{-1}\)) both exhibiting equally high selectivity (>98%).

Isomerization of substituted styrene oxides allows the synthesis of aldehydes in high yields [Eq. (5.275)]. Cycloalkene oxides do not react under these conditions, whereas 2,2,3-trimethyloxirane gives isopropyl methyl ketone (85% yield). Isomerization of oxiranes to carbonyl compounds is mechanistically similar to the pinacol rearrangement involving either the formation of an intermediate carbocation or a concerted mechanism may also be operative. Glycidic esters are transformed to \(\alpha\)-hydroxy-\(\beta,\gamma\)-unsaturated esters in the presence of Nafion-H [Eq. (5.276)].

\[
\text{CH}_2\text{Cl}_2, \text{RT or 40°C, 5–12 h} \quad \text{(5.275)}
\]
Methyloxirane showed a complex pattern of transformations over various solid acids in a pulse microreactor study. \( \text{Nafion-H} \) was found to exhibit the highest activity (30% conversion at 90°C) to produce propanal (about 22% selectivity) and cyclic dimers (substituted 1,3-dioxacycloalkanes, 60% selectivity).

Ring opening of chiral epoxy alcohols with long-chain \( n \)-alcohols was induced by triflic acid (65°C, 4–24 h) to afford mono-\( O \)-alkylated glycerols \( \text{(172)} \). The products are formed in good yields (36–83%) with high regiospecificity [ratio of \( \text{C}(3)/\text{C}(2) \) attack > 10, ee’s > 95%]. 3,3-\( O \)-polymethylene glycerols \( \text{(173)} \) were synthesized in a similar manner using \( \alpha, \omega \)-diols (neat, 82°C, 8–10 h or \( \text{CHCl}_3 \), reflux, 48 h, 36–68% yield).

The ring opening of oxanorbornadiene \( \text{(174)} \) in triflic acid results in the formation of isomeric phenols \( \text{[Eq. (5.277)]} \). Products are formed directly via the rearrangement of the ring \( O \)-protonated oxonium ion intermediate \( \text{(175)} \) or Wheland intermediates may also be involved. The related transformation of the diepoxytetralin \( \text{(176)} \), which includes a Wagner–Meerwein phenyl migration to a carbocation generated by oxirane ring opening, was performed with Nafion-H \( \text{[Eq. (5.278)]} \).
5.15. DEHYDRATION

1,2-Diols are known to undergo the pinacol–pinacolone rearrangement under acidic conditions, including Nafion-H to yield carbonyl compounds with the concomitant elimination of water. Olah, Klumpp, and co-workers have, however, observed that aryl pinacols and epoxides are cleanly and selectively afford condensed aromatics in superacidic triflic acid [Eq. (5.279)]. Although a mixture of isomers were obtained from 1,2-bis(4-fluorophenyl)-1,2-diphenyl-1,2-ethanediol, the transformation of other 1,2-bishalophenyl derivatives and 1,2-bis(2,4-difluorophenyl) diol was regioselective. Acidity-dependence studies with benzpinacol, tetraphenyloxirane, and triphenylacetophenone, the corresponding pinacol rearrangement product ketone, showed that they are all converted to 9,10-diphenylphenanthrene in acid systems with acid strengths greater than $H_0 = -12$—that is, with superacids. This led to the suggestion of a reaction mechanism with the involvement of superelectrophilic protosolvated reactive intermediate 177 [Eq. (5.280)]. Similar observations were made with superacidic BF$_3$–2CF$_3$CH$_2$OH in benzene solution.

$$\text{R} = \text{H, Me, F, Cl}$$

$90–100\%$ yield
Takeuchi and co-workers\textsuperscript{736} have reported that ionization of 3,4-dimethyl-4-homo adamantanol in Magic Acid results in ionization and rearrangement to yield the 3-ethyl-5-methyl-1-adamantyl cation \textsuperscript{178} observed by $^{13}$C NMR spectroscopy at $-30^\circ$C, which, after quenching with methanol, gives ether \textsuperscript{179} [Eq. (5.281)]. A series of known rearrangement steps and intermediates including protoadamantyl cations can account for the observation.

\begin{equation}
\begin{array}{ccc}
\text{OH} & \text{HSO}_3\text{F-SbF}_5 & \text{SO}_2\text{ClF}, -120^\circ\text{C} \\
\text{CH}_3 & \text{CH}_3 & \\
\text{CH}_3 & \text{MeOH quench} & \\
\text{CH}_2\text{CH}_3 & \text{CH}_3 & \\
\text{178} & \text{179} & 71\% \text{ yield}
\end{array}
\end{equation}

Dehydration of alcohol to alkenes usually does not require superacidic conditions. Surprisingly, however, perfluoroalkylcyclopentanols could not be dehydrated with \textit{para}-toluenesulfonic acid, but alkenes could be isolated with the use of the stronger acid Nafion-H albeit in low yields\textsuperscript{737} [Eq. (5.282)].

\begin{equation}
\begin{array}{ccc}
\text{O} & \text{R}_\text{F} & \text{Nafion-H} \\
\text{R}_\text{F} & \text{toluene, reflux, 24 h} & \\
\text{C}_6\text{F}_{13} & \text{C}_8\text{F}_{17} & 47\% \quad 20\%
\end{array}
\end{equation}

Alcohols can undergo acid-catalyzed dehydration to give either the corresponding alkenes or the corresponding ethers. The product distribution of the dehydration of alcohols over Nafion-H catalyst shows temperature dependence\textsuperscript{187} (Table 5.40). Alcohols are thus efficiently dehydrated in the gas phase over Nafion-H under relatively mild conditions with no evidence for any side reactions such as dehydrogenation or decomposition. At higher temperature, olefin formation predominates.

Nafion SAC-13 exhibited the highest activity and selectivity in the dehydration of 1- and 2-hexanol and cyclohexanol to alkenes in the gas phase over various solids in the temperature range of 200–300°C. Furthermore, it did not show the dramatic decrease in activity when compared to zeolites; rather, it exhibited an initial activity increase. This was attributed to solvation of the polymeric matrix by the water vapor formed in the process. This served to swell the resin, rendering previously inaccessible sites available to the reactants.

Low temperature and high alcohol partial pressure were found to favor ether formation in the dehydration of methanol and isobutyl alcohol over Nafion-H. The mixed methyl isobutyl ether as the dominant product, the absence of methyl tert-butyl ether, and large amounts of 2,5-dimethylhexene indicate that free carbenium ions are not involved in the transformations. In a comparative study, Nafion NR50 showed the highest selectivity to form dipentyl ether from 1-pentanol (150–190°C), but its activity was lower than that of Amberlyst resins calculated on a weight basis. Nafion-H has been found to be an excellent catalyst to transform primary alcohols to the corresponding symmetric ethers (reflux temperature, 7–12 h, 92–98% yield), whereas mixed diphenylmethyl ethers of both primary and secondary alcohols were isolated in good to high yields under mild conditions [Eq. (5.283)].

5.16. SUPERACIDS IN CARBOHYDRATE CHEMISTRY

O-Glycosylation—that is, the condensation of a sugar derivative bearing an appropriate functional group (donor) with an appropriately protected other sugar derivative with a free hydroxyl group (acceptor)—is a crucial methodology in carbohydrate and natural product chemistry.

Glycosyl fluorides, widely used reagents in carbohydrate and natural product chemistry, can be used to carry out stereoselective synthesis of glycosides with a catalytic amount (5 mol%) of triflic acid. The appropriately protected β-D-glycosyl fluorides of glucose and galactose as donor molecules, when applied in dichloro-
methane as solvent, afford the corresponding β-d-glycosides\textsuperscript{747,748} (Scheme 5.72). In contrast, the same combination of reagents in diethyl ether solvent leads to the formation of the α-linked disaccharides\textsuperscript{749} (Scheme 5.72). One-pot sequential stereo-selective glycosylation based on this method has been applied for the convergent total synthesis of oligosaccharides.\textsuperscript{750}

Mukaiyama and co-workers\textsuperscript{751} have tested a variety of donor compounds in glycosylation of various acceptor molecules in triflic acid. Glucosyl α-thioformimidates are highly reactive donors and the stereochemistry can be controlled by reaction conditions: In methyl tert-butyl ether at 0°C, α-glycosylation takes place with selectivities up to 90\%, whereas selective β-glycosylation was observed in propionitrile (−78°C, up to 98\% selectivities). In a comparative study with various donors in triflic acid, 6-nitro-2-benzothiazolyl α-glucoside showed the highest β-selectivity\textsuperscript{752} [Eq. (5.284)].

\[
\begin{array}{cccc}

\text{R} & \text{OMe, R} & \text{H} & \text{BnO, R'} & \text{H} \\
\end{array}
\]
Wong and co-workers\textsuperscript{753} and Hashimoto and co-workers\textsuperscript{754} have demonstrated that triflic acid is an ideal promoter in chemo- and stereoselective glycosylation with phosphites [Eq. (5.285)].

\begin{equation}
\begin{array}{c}
\text{BnO} & \text{BnO} & \text{BnO} & \text{BnO} & \text{BnO} & \text{BnO} \\
\text{O} & \text{P(OBn)}_2 \\
\text{HO} & \text{O} & \text{O} & \text{O} & \text{OMe} & \text{OMe} \\
\end{array}

\end{array}
\end{equation}

Franck and Marzabadi\textsuperscript{755} have developed the heterocyclic donor 180 and used it in coupling with a variety of alcohol acceptors to obtain β-glycosides in good yields with excellent stereoselectivities using equimolar amount of triflic acid [Eq. (5.286)].

\begin{equation}
\begin{array}{c}
\text{BnO} & \text{BnO} & \text{BnO} & \text{BnO} & \text{S} \\

\text{R = Me, allyl, Bu, Ph, Bn} \\
\text{70\% yield} \\
\beta = 100 \\
\end{array}
\end{equation}

Catalytic amount (5 mol\%) of triflic acid has been shown to be effective in the intramolecular condensation–dehydration-type glycosylation to form anhydroketo-pyranoses without the necessity to introduce any leaving groups\textsuperscript{756} [Eq. (5.287)]. Interestingly, the twist-boat conformers were also detected in the transformation of the 1-phenyl- and 1-benzyl-susbtituted compounds.

\begin{equation}
\begin{array}{c}
\text{BnO} & \text{BnO} & \text{BnO} & \text{BnO} & \text{OH} \\
\text{R = Me, allyl, Bu, Ph, Bn} \\

\end{array}
\begin{array}{c}
\text{BnO} & \text{BnO} & \text{BnO} & \text{BnO} \\
\text{70–93\% yield} \\
\end{array}
\end{equation}
In another application of catalytic glycosylation with triflic acid, two disaccharides were synthesized with donors bearing trichloroacetimidate function and then the disaccharides thus prepared were condensed in a similar manner to a tetrasaccharide\(^7\) (1,2-dichloroethane, 55°C, 1.5 h, 50–85% yields). The same protocol was used in the synthesis of a decasaccharide from mono-, tetra-, and pentasaccharide building blocks. The trichloroacetimidate procedure has been successfully used in the glycosylation of \(\beta\)-cyclodextrins promoted by triflic acid.\(^7\)

Glycosylations can also be effectively induced with Nafion-H.\(^7\) Protected mannopyranosyl-1-\(\alpha\)-sulfoxide reacts with alcohol acceptors to yield \(\alpha\)-glycosides with high stereoselectivity\(^7\) [Eq. (5.288)]. In fact, the sulfoxide method using arylsulfoxide derivatives as the donor and an appropriate scavenger in triflic acid has been successfully applied in the synthesis of di- and oligosaccharides\(^7\) and in the coupling of unreactive nucleophiles as glycosyl acceptors.\(^7\)

![Equation (5.288)](image)

Yield, % 94 99 94 97 90 80
\(\alpha/\beta\) 97/3 96/4 97/3 97/3 98/2 96/4

Neighboring group participation by substituents such as a PhS group at an adjacent carbon atom has long been considered to control stereochemistry in glycosylation. Sulfonium ions, for example, thiranium ion \(181\), have often been postulated to be involved; moreover, such ions have been observed by low-temperature NMR spectroscopy (see Section 4.2.2.4). The participation of sulfonium ions as reactive intermediates in glycosylation, however, has recently been disputed. Woerpel and co-workers\(^7\) have analyzed the stereochemistry of various glycosylation reactions and computed possible reaction intermediates. They concluded that the bridged form (\(181\)) equilibrates with the open carboxonium ion form (\(182\)), and the latter should be the precursor to the products if electron donation from oxygen is more stabilizing than anchimeric assistance from sulfur.
C-2-Methylene α-glycosides 183 and 184 are readily synthesized by reacting C-2-acetoxymethyl glycals with alcohols in the presence of Nafion-H\(^\text{763}\) [Eq. (5.289)]. Unexpectedly, para-cresol gave the corresponding β-glycoside, whereas β-naphthol afforded a C-glycoside. Facile chemoselective deprotection at room temperature of terminal isopropylidene acetals (2–4 h, 68–96% yields) and trityl ethers (7–14 h, 75–92% yields) with Nafion-H in methanol has also been reported.\(^\text{767}\) Nafion SAC-13 showed high stereoselectivity in the condensation of glucosyl imidate with protected glucose at low temperature (66% yield, β/α = 13.3, −20°C, 4 h).\(^\text{768}\)

![Diagram of reactions](image)

Triflic acid has been applied in the transformation of monosaccharides into spiroketalts (dianhydrides).\(^\text{769,770}\) 3,4,6-Tri-O-protected 1,2-O-isopropylidene-β-d-fructofuranoses undergo a tandem acetal cleavage–intramolecular glycosylation–intramolecular spiroketalization process in the presence of triflic acid to give binary mixtures of α,α and α,β diastereomeric products [Eq. (5.290)]. The isomer ratio strongly depends on the nature of the protecting groups. Ether groups prefer the nonsymmetric α,β distereomer, whereas the benzoyl group favors the symmetric α,α diastereomer. Similar observations were made in the transformation of d-fructopyranose derivatives. The method has recently been used in the synthesis of d-fructose spiroketals attached to xyylene tethers.\(^\text{771}\) Anhydrous hydrogen fluoride and pyridinium poly(hydrogen fluoride) (PPHF) were also used in the synthesis of oligosaccharides with spiroketal moieties.\(^\text{772}\)
Fused or spiro sugar oxazolines have been synthesized by treating D-fructopyranose or D-fructofuranose 1,2-\(\text{O}\)-acetonides with nitriles in triflic acid\(^{773}\) (Scheme 5.73). First the activation of the anomeric center takes place with simultaneous isopropyridene cleavage to form the oxocarbenium ion intermediate, which is attacked by the nitrile. The resulting nitrilium ion is then trapped by the hydroxyl group in an intramolecular Ritter-like reaction to yield the final product.

Anhydrous hydrogen fluoride has been successfully applied in the structural analysis of polysaccharides to cleave glycosidic linkages since the 1980s. Recently, triflic acid has been found to be a more potent and more selective agent.\(^{774}\) In structural studies, for example, polysaccharides isolated from bacteria were stable toward
solvolysis in anhydrous HF. Triflic acid, in turn, selectively cleaved glycosidic linkages without affecting amide-like substituents.\textsuperscript{775,776}

5.17. REARRANGEMENTS AND CYCLIZATIONS

5.17.1. Rearrangements and Cyclizations of Natural Products

Acid-catalyzed rearrangements of natural products, particularly those of terpenes, which often involve cyclization, have been studied extensively.\textsuperscript{777–784} This research has unraveled numerous unique rearrangements that are both synthetically and mechanistically significant. Moreover, the recognition that cationic cyclizations play a key role in biogenesis\textsuperscript{777,785–789} of isoprenoids (terpenes) has provided incentive to mimic in vitro\textsuperscript{790–792} many of these rearrangements by generating the appropriate carbocations.

The literature abounds with examples of rearrangement of a wide variety of terpenoids with varying acid catalysts.\textsuperscript{777–784} One of the most significant areas is the synthesis of triterpenoids by van Tamelen,\textsuperscript{790} Johnson,\textsuperscript{791} and others. However, most of these rearrangements have been studied under mild conditions, in nucleophilic media with relatively weak acids. Under these conditions of low acidity, only a very minute amount of the reactants exists as carbocation at any time because the electron-deficient intermediates react immediately with available nucleophiles, both external and internal via a number of competitive, irreversible reactions. In other words, only short-lived, transient intermediates are involved. Consequently, quite often, complex mixtures of products are formed in the rearrangements during mild acid catalysis, because the products obtained are generally comparable in energy content. In addition, products with more than two carbocycles could not be obtained in high yields.

The use of carbocation-stabilizing superacids such as HSO\textsubscript{3}F, HSO\textsubscript{3}F–SbF\textsubscript{5}, CF\textsubscript{3}SO\textsubscript{3}H, HF–SbF\textsubscript{5}, HF–BF\textsubscript{3}, and so on, to alter the normal course of acid-catalyzed rearrangements has offered unique possibilities, since the stable carbocation would have time to explore many internal escape paths (through a probably shallow potential energy surface) but would not convert to neutral products. In recent decades, considerable progress has been made in this area, especially by the pioneering work of Jacquesy\textsuperscript{784} and the wide-ranging studies by Vlad\textsuperscript{793} and Barkhash and Polovinka.\textsuperscript{794}

As early as 1893, it was discovered\textsuperscript{795} that camphor \textbf{185} rearranges to 3,4-dimethylacetophenone \textbf{186} in concentrated H\textsubscript{2}SO\textsubscript{4} and the mechanism of the reaction has been elucidated by Roberts\textsuperscript{796} and Rodig\textsuperscript{797} [Eq. (5.291)].

\[
\begin{align*}
\text{Camphor} (\textbf{185}) & \xrightarrow{\text{H}_2\text{SO}_4} \text{3,4-Dimethylacetophenone} (\textbf{186}) \\
\end{align*}
\]  
\text{(5.291)}
However, Jacquesy and co-workers\textsuperscript{784,798} have shown that in superacidic HF—SbF\textsubscript{5} medium, the reaction takes a different course. Camphor gives a mixture of three ketones [Eq. (5.292)].

\[
\begin{align*}
\text{185} & \xrightarrow{\text{HF–SbF}_5, 24 \text{ h}} \text{187} + \text{188} + \text{189} \\
\end{align*}
\]

(5.292)

Sorensen and co-workers\textsuperscript{799–801} have studied the fate of observable camphene hydrocation 190 prepared from isoborneol 187, camphene 188, or tricyclene 189 in HSO\textsubscript{3}F acid medium (Scheme 5.74). The intermediate cycloalkenyl cation 191 can also be prepared by protonation of \(\alpha\)-terpineol (192), sabine (193), and \(\beta\)-pinene (194) (Scheme 5.75).
An early example is the fascinating rearrangement of acyclic monoterpenes geraniol 195 and nerol 196 to a stable observable oxonium ion in HSO₃F—SO₂—CS₂ at −78°C, which represents yet another dramatic example of altered course of terpene rearrangement in superacid medium. Careful quenching of this ion led to the isolation of 3β,6α,6αβ-trimethyl-cis-perhydrocyclopenta[b]furan 197 in excellent yield (Scheme 5.76).
In a subsequent study, however, Whittaker and co-workers\textsuperscript{803} showed that the product formed from geraniol, in fact, is the isomeric bicyclic ether 198. It was also shown that cyclization of citronellal in HSO$_3$F\textendash SO$_2$ at $-78^\circ$C affords pulegol and neoisopulegol; that is, the transformation parallels closely the reaction in normal acids.\textsuperscript{804}

Whittaker and co-workers\textsuperscript{805,806} have also prepared a number of terpenoid bicyclic ethers, such as isomeric 1,6-dihydrocarveols 199 (HSO$_3$F\textendash SO$_2$, 78$^\circ$C) from unsaturated alcohols or diols.\textsuperscript{805,806} para-Menth-1-en-9-ol and a related diol afforded the seven-membered ring systems 200. The oxolane moiety in compound 201 was generated from the corresponding unsaturated alcohol precursor in 2 equivalents of triflic acid.\textsuperscript{807}

Fluorosulfuric acid is a widely used, highly effective reagent\textsuperscript{808} in electrophilic polyene cyclizations to synthesize fully cyclized compounds in a selective and stereospecific way. Furthermore, an internal nucleophile, most often oxygen, allows the construction of polycyclic skeletons with a heteroatom (\textit{vide supra}). Snowden and co-workers\textsuperscript{809} transformed trienone 202 (a mixture of 4 diastereomers) into three isomeric irone derivatives [Eq. (5.293)]. Other acids gave inferior results.

\[
\begin{align*}
\text{202} & \xrightarrow{\text{HSO}_3\text{F}} \text{70\% yield} \\
\text{202} & \xrightarrow{\text{2-nitropropane, } -70^\circ\text{C, 1 h}} \text{70\% yield}
\end{align*}
\]
Structurally related dienols and acyclic trienols, when reacted in fluorosulfuric acid, give tricyclic ether derivatives in kinetically controlled cyclization.\textsuperscript{810,811} The stereospecific product formation is rationalized by synchronous internal anti-addition via chair-like conformations of the protonated cyclohexene ring, resulting in ring closure with equatorial C–C bond formation and concomitant internal nucleophilic termination by anti-addition of the OH group [Eq. (5.294)]. \textit{Z}/\textit{E} isomerization may be competitive with cyclization.

\begin{equation}
\begin{array}{c}

Chlorosulfuric acid used less frequently has been shown to be equally effective in related transformations. Altarejos, Barrero, and co-workers\textsuperscript{812,813} carried out superacid-mediated cyclizations including the transformation of trienol 203 to racemic ambrox (204a) and \textit{epi}-ambrox (204b) constituents of ambergris fragrances [Eq. (5.295)]. Isomeric \textit{\beta}-monocyclofarnesol and -nerolidol and their acetates gave a single unique rearranged ocathydromethanol product in chlorosulfuric acid under similar conditions (2-nitropropane, -78°C, 10 min)\textsuperscript{814} [Eq. (5.296)].

\textit{(5.296)}
Vlad and co-workers have made extensive studies of the superacidic cyclization of terpenoids. Early results have been summarized in a review.\textsuperscript{793} Subsequently, they reported the superacidic low-temperature cyclization of terpenols and terpenol acetates to form homoallylic alcohols or hydroxy acetates of cyclized terpenols, respectively\textsuperscript{815} (Schemes 5.77 and 5.78). The transformations are highly efficient, chemo- and structurally selective, and stereospecific. The configuration of the hydroxymethyl (acetoxymethyl) group is determined by the configuration of the allylic double bond of the precursor (Schemes 5.77 and 5.78). Terpenoid acids and esters,\textsuperscript{816,817} as well as phenylsulfones,\textsuperscript{818,819} also undergo stereoselective cyclization in the presence of $\text{HSO}_3\text{F}$. In bicyclic stereoisomeric compounds, the internal (13\textsubscript{Z}) C=C double bonds were shown to affect the selectivity of cyclization.\textsuperscript{817} In the transformation of isomeric methyl (6\textsubscript{Z})-geranylgeranoates in $\text{HSO}_3\text{F}$ the (6\textsubscript{Z}) double bond plays a key role to form steroisomeric tricyclic products.\textsuperscript{820}
Vlad and co-workers\textsuperscript{821} have also found that the cyclization of stereoisomeric farnesols proceeds regioselectively and stereospecifically in HSO\textsubscript{3}F−SO\textsubscript{2}ClF to yield drimenol \textbf{205} (Scheme 5.79) and epi-drimenol, respectively. The configuration of the C(6)−C(7) double bond does not affect the stereochemistry. When \textbf{205} or trans,trans-farnesol \textbf{206} was dissolved in HSO\textsubscript{3}F−SO\textsubscript{2}ClF at −115°C and the solution was warmed to −70°C, the tricyclic oxolane derivative \textbf{207} was isolated (Scheme 5.80). Recently, they have successfully carried out the cyclization of several aliphatic sesquiterpene derivatives (\textit{E,E}-farnesol and its acetate, \textit{E,E}-farnesyl phenylsulfone, and the methyl ester of \textit{E,E}-farnesylic acid) with HSO\textsubscript{3}F in ionic liquids ([BMIM] [BF\textsubscript{4}], [BMIM][PF\textsubscript{6}]).\textsuperscript{822}
They have also reported the transformation of all-trans-\(\omega\)-acetoxyfarnesol benzyl ether to afford a mixture of two stereoisomers in a clean reaction\(^\text{823}\) [Eq. (5.297)]. In sharp contrast, the hydroxy compound gave a complex mixture of products. The selective reaction of the acetoxy derivative was interpreted as resulting from a rare example of initial protonation of the internal \(\text{C}(6)\text{--C}(7)\) double bond.

Barkhash and Polovinka\(^\text{794}\) have reported in a series of papers the results of their extensive studies of the transformations of a large number of terpenoids induced by homogeneous and heterogeneous acids including fluorosulfuric acid. 2,3-Epoxygeraniol 208 was shown previously by Whittaker and co-workers\(^\text{824}\) to afford epimeric oxabicyclooctanes in \(\text{HSO}_3\text{F}\text{--SO}_2\) at 70°C [Eq. (5.298)]. Repeating the transformation at lower temperature (\(-100^\circ\text{C}\)) and quenching the reaction mixture by methanol/ether, Barkhash and co-workers isolated the tetrahydropyranyl derivative 209 (Scheme 5.81).\(^\text{825}\) Quenching at \(-80^\circ\text{C}\) gave, in addition to compound 209, one of the oxabicyclooctane isomers and isomeric dehydrooxepanes.
Cyclic epoxide derivatives, such as 2,3-epoxy-\textit{cis}-pinane 210 [Eq. (5.299)]\textsuperscript{826} and isomeric caryophyllene diepoxides 211 [Eq. (5.300)],\textsuperscript{827} undergo varied transformations including ring contraction under similar conditions.

Alkenes of the aromadendrane series rearrange into tricyclic ring systems in fluorosulfuric acid\textsuperscript{828} [Eq. (5.301)]. The transformation of related compounds under similar conditions and calculations suggest the involvement of cation 212 as the key intermediate.
Additional examples are the clean ring opening transformation of cis- and trans-3-methyl-cis-verbanone\(^{829}\) [Eq. (5.302)]. Product structures indicate that there is no epimerization at C(3) (in the starting materials) and C(6) (in the products) despite the strongly acidic conditions. The ring opening and rearrangement shown in Eq. (5.303) are key steps in the synthesis of a marine nor-sesquiterpene.\(^{830}\)
Collado and co-workers made detailed studies of the chemistry of the sesquiterpenoid caryophyllene and its hydroxylated products including rearrangements induced by superacids.\textsuperscript{831} They have recently reported\textsuperscript{832} novel rearrangements of the sesquiterpenoid panasinsane derivatives 213 to provide three products and interpreted the transformations by the involvement of the common carbocationic intermediate 214 [Eq. (5.304)].

\begin{equation}
\text{R} = \text{Me}, \text{R'} = \text{OH} \quad 213a \\
\text{R} = \text{OH}, \text{R'} = \text{Me} \quad 213b
\end{equation}

Triflic acid has been used to induce cyclization of polyisoprene (xylene, 75°C, 5–30 min) and the various ring moieties (215–217) were identified by $^1\text{H}$ NMR.\textsuperscript{833} Farnum, Mehta, and co-workers\textsuperscript{834,835} have shown that longifolene 218 and isolongifolene 219 in HSO$_3$F media give a mixture of cyclohexenyl cations at different temperatures. Quenching these cations provides some unusual sesquiterpene like C$_{15}$-hexahydronaphthalenes 220–225 (Scheme 5.82).
The rearrangement of some resin acids 226, 227, and 228 in superacidic HSO₃F and
HSO₃Cl media has also been studied. Jacquesy and et al. 838,839 have developed a
novel isomerization of pregnan-3,20-diones 229 to mixture of isomers that also
contains 13α isomers. The reaction is proposed to occur through the cleavage of
C(13)–C(17) bond (Scheme 5.83).

Similarly, HF–SbF₅-induced isomerization of androsta-4,6-diene-3,17-dione 230
has been studied in detail, 840 which led to a new entry into the 9-methylsterane series
231. Also, methods have been developed for the synthesis of isosterane derivatives 841
and other methyl-substituted estrane dione derivatives of unnatural configurations. 842
HF–SbF₅ superacid medium is also capable of demethylating aromatic ethers. This
reaction has been successfully employed in the synthesis of 11-deoxyanthracyclines
232 [Eq. (5.305)]. 843
In a series of papers, Jacquesy and Jouannetaud have demonstrated the efficacy of aromatic cyclization reactions in HF–SbF₅ medium. ¹³⁸ ¹,³-Bis(methoxyphenyl) propanes and other substituted phenylpropanes 2³³ give substituted indenes (2³⁴) and tricyclic spiro enones (2³⁵) in the superacid medium ⁸⁴⁴ (Scheme 5.84).
1,2-Bis(methoxyphenyl)ethanes subjected to a similar treatment (HF−SbF₅, 0°C, 5–270 min) gave tetrahydrophenanthrene derivatives [Eq. (5.306)].
This cyclization method has been applied in the synthesis of the C-ring aromatic analog, 4-androstene-3,17-dione derivative 236. Two cyclizations and the subsequent hydroxylation take place under superacidic conditions [Eq. (5.307)].

Monocyclic phenols and their methyl ethers react with benzene in HF–SbF₅ medium to provide 4,4-disubstituted cyclohexenones 237 [Eq. (5.308)]. para-Methylanisole gives three products: two cyclohexenone derivatives [see Eq. (5.112)] and an interesting tricyclic ketone 238.
By utilizing the above methods, a convenient route to the tetracyclic ketone 240, a derivative of the benzobicyclo[3.2.1]octane skeleton, has been developed using 2'-methoxy-5'-methyl-1,3-diphenylpropane 239 (Scheme 5.85).

Zhao and co-workers synthesized macroreticular para-($\omega$-sulfonic-perfluorooalkylated) polystyrene (FPS) and used it in the cyclization of pseudoionone into $\alpha$-ionone 241a an important fragrance material. The ring closure induced by the catalyst led to complete conversion and the product was formed in low yield but selectively ($\beta$-ionone was not observed) [Eq. (5.309)]. Amberlyst proved to be less active and less selective. A new catalyst loaded with perfluoroalkanesulfonic as well as phenylsulfonic acid groups (FPSS) exhibited improved performance [Eq. (5.309)].
5.17.2. Phenol–Dienone Rearrangements

Conversion of phenol to a dienone and vice versa is an important transformation and is widely used in organic natural product synthesis. Jacquesy and co-workers\textsuperscript{850} have demonstrated that this rearrangement occurs very efficiently in superacid solutions. Treatment of estrone derivatives \textsuperscript{242} in HF–SbF\textsubscript{5} followed by aqueous bicarbonate work up led to estra-4,9-diene-3,7-dione \textsuperscript{243} \[\text{Eq. (5.310)}\]. The reaction also occurred in HSO\textsubscript{3}F–SbF\textsubscript{5} medium. The intermediate tricationic species and their isomers of the above rearrangement process have been characterized by \textsuperscript{1}H NMR spectroscopy.\textsuperscript{851,852} Coustard and Jacquesy\textsuperscript{853} have also investigated as models, the rearrangement of simple bicyclic phenols and phenolic ethers in HF–SbF\textsubscript{5} or HSO\textsubscript{3}F–SbF\textsubscript{5} medium [Eq. (5.311) and Scheme 5.86].
Similarly, many A-norsteroids 244 have been subjected to phenol–dienone rearrangement in HF–SbF₅ medium⁸⁵⁴ [Eq. (5.312)]. ¹H NMR spectroscopic studies at low temperature confirms the formation of O-protonated intermediates (Scheme 5.87), which subsequently rearrange to diprotonated precursors of the dienones 245.

Androsta-1,4,6-triene-3,17-dione 246, when treated with ordinary acid catalysts such as acetic anhydride–para-toluenesulfonic acid, gives the meta phenolic product 247 (Scheme 5.88). However, under HF–SbF₅ catalysis at −50°C the phenolic product 248 is obtained in 75% yield⁸⁵⁵ (Scheme 5.88). The mechanism of the above discussed phenol–dienone and dienone–phenol rearrangement has been investigated in detail.⁸⁵⁶,⁸⁵⁷
A related transformation is the rearrangement–aromatization of ketoisophorone to trimethylhydroquinone diacetate, an intermediate in the industrial synthesis of (all-
rac)-α-tocopherol. Of heterogeneous catalysts, Nafion–silica exhibited the best catalytic activity\(^{858}\) [Eq. (5.313)], but activities decreased with repeated use because of the leaching of Nafion resin.

\]

\[5.17.3. \text{Other Rearrangements and Cyclizations}\]

Sheldon and co-workers\(^{859}\) have performed the cyclization of \(N\)-formyl enamide 249 in triflic acid or over Nafion-H to form the corresponding \(N\)-formylotahydroisoquinolines starting compounds in the synthesis of \(N\)-formylmorphinanenes [Eq. (5.314)].
A novel one-pot tandem oxidation–cyclization–oxidation process was successfully applied in the transformation of unsaturated alcohols \(250\) [Eq. (5.315)].\(^{360}\) The intermediate aldehyde formed by oxidation with pyridinium chlorochromate (PCC) undergoes a carbonyl–ene cyclization followed by an additional oxidation to form 3-substituted piperidinones.

(5.316)

Isomerization of pivalaldehyde to yield isopropyl methyl ketone has been shown by Olah et al.\(^{451}\) to strongly depend on the acidity. Triflic acid, anhydrous HF, and \(\text{BF}_3–2\text{CF}_3\text{CH}_2\text{OH}\), but not trifluoroacetic acid, induce quantitative isomerization; that is, acids with \(H_0 \leq -11\) are required for complete isomerization. These observations and DFT calculations (B3LYP/6-31G* level) suggest that protonation (protosolvation) of protonated pivalaldehyde forms the reactive superelectrophilic species \(252\) [Eq. (5.317)]. Gitonic dication \(252\), however, is not a minimum on the potential energy surface and is transformed to the most stable distonic dication \(253\).
(the global minimum) in a barrierless process. Formation of dication 252 increases the electrophilic character of the protonated carbonyl oxygen leading to methyl shift, which alleviates the electron demand in the adjacent position. Gitonic dication 252 was estimated to be 48 kcal mol\(^{-1}\) less stable than distonic dication 253.

\[ \text{H}_3\text{C} - \text{C} - \text{C} - \text{H} \rightarrow \text{H}_3\text{C} - \text{C} - \text{C} - \text{H} \quad 252 \]

\[ \text{H}_3\text{C} - \text{C} - \text{C} - \text{H} \quad 253 \]

By studying stable ion chemistry of polycyclic aromatic systems, Laali et al.\(^{862}\) observed the ring closure of dicyanometacyclophanediene 254 with the involvement of diprotonated intermediate 255 [Eq. (5.318)]. When product 256 was treated again in superacids under different conditions, rearrangement took place to yield 1-cyanopyrene through mono- and diprotonated intermediates [Eq. (5.319)].

\[ \text{H}_3\text{C} - \text{C} - \text{C} - \text{H} \quad 254 \quad \text{HSO}_3\text{F} - \text{SO}_2\text{ClF} -78^\circ\text{C} \quad \text{quench} \quad 255 \quad \text{R} = \text{CNH} \quad 256 \quad + \quad 254 \]

\[ \text{R}_+ \quad 255 \quad \text{quench} \quad + \quad 254 \]

\[ \text{HSO}_3\text{F}, \text{or} \quad \text{HSO}_3\text{F} - \text{SbF}_5 \quad (4:1 \text{ or } 1:1) \quad \text{SO}_2\text{ClF}, -78^\circ\text{C} \quad \text{quench} \quad + \quad 254 \quad + \quad 256 \]

\text{major product}
Karpov and co-workers\textsuperscript{290,660,863,864} have performed extensive studies with respect to the transformation of perfluorinated benzocyclobutene, indane, tetralin, their perfluoroalkyl-substituted, and mono- and dioxo derivatives in HF–SbF\textsubscript{5} or SbF\textsubscript{5} at elevated temperatures. Complex product mixtures are usually obtained resulting from ring cleavage, ring expansion and ring contraction. Product distributions strongly depend on temperature and the quantity of SbF\textsubscript{5} used. For example, compounds 257, 258, and 259 could be isolated in modest yields (10–58\%), when perfluoro-3-ethylindan-1-one was treated in excess SbF\textsubscript{5} followed by quenching with hydrochloric acid.\textsuperscript{865} Cations 260 and 261 were detected by \textsuperscript{19}F NMR spectroscopy.

In the presence of SiO\textsubscript{2} serving as the oxygen source, complex mixtures of rearranged oxygenated compounds are formed. As the transformation of perfluoro-1-ethylindane (262) shows, however, products may be isolated in high yields under appropriate conditions\textsuperscript{865} [Eq. (5.320)].

\end{align*}

\textbf{5.18. IONIC HYDROGENATION}

In catalytic hydrogenations, usually hydrogen is activated (generally by noble metal catalysts). In contrast, in ionic hydrogenations an acid catalyst activates the hydrocarbon-forming carbocationic sites, which then are quenched by hydrogen to reduced products. A significant number of ionic hydrogenations were studied and a review of earlier work is available.\textsuperscript{866} Hydride transfer in superacidic media is a very versatile reaction, especially in isomerization and cracking of hydrocarbons (Sections 5.1.3 and 5.1.4). The reaction has been extensively employed in liquefaction of coal using
tetralin, methylcyclopentane, and so on, as hydride donors in the presence of strong Lewis acids. In fact, Olah and co-workers have found that coal can be depolymerized in the presence of HF–BF₃ under hydrogen pressure at modest temperatures (100–170°C). Addition of isopentane to this reaction substantially improved depolymerization (vide supra). The related hydrogenation of benzene has been studied using HF–TaF₅ and HF–SbF₅ as catalyst. Another early example is the use of BF₃–H₂O in combination with triethylsilane to reduce anthracene, naphthacene, and hydroxy- and methoxynaphthalenes to the corresponding di- or tetrahydroderivatives. 2-Acetonaphthalene and adamantanonewere transformed to the corresponding parent hydrocarbons, whereas benzene, substituted benzene derivatives, naphthalene, and phenanthrene could not be reduced.

The hydride transfer reaction catalyzed by strong acids has also been successfully adapted in the natural product chemistry. Jacquesy et al. have found that protonated dienones and enones of steroid nucleus can be conveniently reduced in HF–SbF₅ medium under hydrogen pressure. The reaction has also been carried out with added hydrocarbons (methylcyclopentane, cyclohexane) as hydride donors. The proposed mechanism is depicted in Scheme 5.89.

As model studies, several bicyclic compounds have also been reduced using cyclohexane in HF–SbF₅ [Eq. (5.321)]. 2-Hydroxytetralin undergoes phenol–dienone rearrangement before reduction. Estrone and an unsaturated estrane have been reduced in HF–SbF₅ medium under hydrogen pressure yielding an anthrasteroid, whose structure and absolute configuration have been determined.

\end{align*}
\]
In a series of papers, Koltunov, Repinskaya, and co-workers\textsuperscript{874–877} have reported the ionic hydrogenation of isomeric naphthols and dihydroxynaphthalenes with alkanes in the presence of aluminum halides. 1-Naphthol and substituted derivatives undergo regioselective reduction under mild conditions in excess alkane and aluminum halides with the involvement of various reactive intermediates to yield \( \alpha \)-tetralone derivatives\textsuperscript{874} [Eq. (5.322)]. Byproducts are 3-, 6-, and 7-alkyl-substituted derivatives. Mechanistic studies\textsuperscript{875} with cyclohexane-\( d_{12} \) showed that deuterium incorporation takes place exclusively at C(4), indicating the involvement of super-electrophilic dication \textsuperscript{263}. 2-Naphthol is much less reactive and complete conversion cannot be achieved.\textsuperscript{876}

- \( R = \text{H, 4-Me, 4-Cl, 3-Ph} \)

When isomeric 1,5-, 1,6-, and 1,7-dihydroxynaphthalenes are reacted under similar conditions,\textsuperscript{877} quantitative formation of the corresponding hydroxy-substituted \( \alpha \)-tetralones were observed. Results were interpreted by invoking the superelectrophilic tricationic complex intermediate \textsuperscript{264}. In a similar manner, the 1-hydroxy-substituted ring is reduced regioselectively when 5-amino-1-naphthol is reacted with cyclohexane in the presence of superacidic AlCl\(_3\), AlBr\(_3\), triflic acid or triflic acid–SbF\(_5\).\textsuperscript{293} In the Brønsted superacids, \( N,C \)-diprotonated dication \textsuperscript{265} is suggested as the superelectrophilic intermediate.

Detailed studies have been reported of the ionic hydrogenation of isomeric hydroxyquinolines and hydroxyisoquinolines. 5-, 7-, and 8-hydroxyquinolines are
selectively reduced with cyclohexane in the presence of aluminum chloride to yield 5,6,7,8-tetrahydroquinoline.\textsuperscript{295} 5-Hydroxyisoquinoline shows a similar transformation in triflic acid–SbF\textsubscript{5}.\textsuperscript{294} As shown by the example of 5-hydroxyquinoline, the probable mechanism (Scheme 5.90) involves the stepwise selective ionic hydrogenation of superelectrophilic dications \textsuperscript{266}, \textsuperscript{267}, and \textsuperscript{268}. 5- and 8-hydroxyquinolines exhibited the highest reactivity, whereas 6-hydroxyquinoline proved to be inert toward cyclohexane. This is in agreement with calculations showing 6-hydroxyquinoline to be the weakest nucleophile on the basis of LUMO energies (B3LYP/6-31G*) and atomic charges (NBO analysis) on the reaction center.

Isomeric 2- and 4-hydroxyquinolines undergo selective ionic hydrogenation with cyclohexane in triflic acid–SbF\textsubscript{5} to produce the corresponding 5,6,7,8-tetrahydroquinolinones (83\% and 92\% yields), whereas 3-hydroxyquinoline gives 5,6,7,8-tetrahydro-3-quinolinol in 72\% yield.\textsuperscript{878} NMR spectroscopy showed that the three isomeric hydroxyquinolines undergo monoprotonation in triflic acid, whereas 3-hydroxyquinoline gives the \textit{N},\textit{C}-diprotonated species \textsuperscript{269} in the more acidic triflic acid–SbF\textsubscript{5} system.
When 1-, 3-, and 8-hydroxyisoquinolines are treated with AlCl$_3$ isomeric tetrahydroisoquinolinones 270 and 271 are formed, whereas selective formation of the corresponding 5,6,7,8-tetrahydroisoquinolinone 270 is found in the presence of triflic acid–SbF$_5$ [Eq. (5.323)]. Quinoline also undergoes hydrogenation upon treatment in CF$_3$SO$_3$H–SbF$_5$ system (room temperature, 24 h) or in HBr–AlCl$_3$–CH$_2$B$_2$ (70°C, 150 h) to yield 5,6,7,8-tetrahydroisoquinoline as the sole product. 297 Isoquinoline exhibits higher reactivity in CF$_3$SO$_3$H–SbF$_5$ (94% yield in 2 h). The observations, again, were interpreted by invoking superelectrophilic dicationic intermediates.

During the reductive isomerization of 7β-methyl-14-isoestr-4-ene-3,17-dione 272 in HF–SbF$_5$/methylcyclopentane at 0°C, it was found that a 1,3-hydride shift occurs followed by kinetically controlled hydride transfer (Scheme 5.91). The mechanism of the reaction was confirmed by employing the deuteriated donor cyclohexane-$d_{12}$ as well as a specifically deuterium-labeled starting steroid.

The ionic transfer hydrogenation in superacidic media has also been studied in the case of bicyclo[4. $n$.0]enones under both kinetic and thermodynamic control.
Kinetically controlled hydride transfer between the hydrocarbon hydride source and the substrate often involves skeletal rearrangements. This has also been demonstrated in the reduction of androsta-4,6-diene-3,17-dione \(230^{,882}\).

Ionic hydrogenation of \(\alpha, \beta\)-unsaturated ketones has been studied by Koltunov et al.\(^{883}\). A variety of \(\alpha, \beta\)-unsaturated ketones reacts with cyclohexane in the presence of excess aluminum chloride or bromide to yield the corresponding saturated ketones in high yields [Eq. (5.324)]. Similar observations were made using triflic acid–SbF\(_5\). The only exception is 4-phenyl-2-butanone, which produces a mixture of products including alkylated derivatives. The reactive intermediates are likely to be C-protonated complexes (when aluminum halides are used) or the \(O, C\)-protonated analogs (in triflic acid–SbF\(_5\)). A few \(\alpha, \beta\)-unsaturated carboxamides could also be reduced to the corresponding saturated amides with cyclohexane in excess AlCl\(_3\).\(^{178}\)

![Chemical structure](image)

Jacquesy and co-workers\(^{884}\) have reported the stereoselective ionic hydrogenation of \textit{Vinca} alkaloids to produce the corresponding 4\(R\) reduced analogs (Scheme 5.92). Mechanistic studies with cyclohexane-\(d_{12}\) showed that deuterium incorporation takes place exclusively at C(20\(^{,97}\)).

![Mechanistic Scheme](image)

\[\text{Scheme 5.92}\]
Ionic hydrogenation can be used to reduce alcohols and it is a convenient way to transform carbonyl compounds to the corresponding methylene derivatives. Olah et al.\textsuperscript{885} have reported that 2-aryladamantanes and 3-aryldiamantanes were isolated in near-quantitative yields by reducing the corresponding tertiary alcohols with NaBH\(_4\) or formic acid in superacidic triflic acid. The NaBH\(_4\)-triflic acid system was also used to carry out a single-step reductive isomerization of unsaturated polycyclics to C\(_{4n+6}\)H\(_{4n+12}\) diamondoid cage hydrocarbons.\textsuperscript{886} Tertiary and benzylic alcohols are also reduced with trialkylboron–triflic acid\textsuperscript{887} [Eq. (5.325)]. Trimethylboron is nonselective producing about 1:1 mixtures of the methylated and reduced products. Triisopropylboron–triflic acid was also reported to selectively convert a variety of hydroxy-substituted carbonyl compounds (carboxylic acids, aldehydes, ketones) to the corresponding carbonyl compounds.\textsuperscript{888} NaBH\(_4\)-triflic acid is also effective in methanation; that is, it reduces CO, CO\(_2\), CS, CS\(_2\), methanol, and formic acid to methane under mild conditions.\textsuperscript{889}

\[

\end{array}
\]

90–100\% yield \hspace{1cm} (5.325)

Various reagents such as Et\(_3\)SiH–triflic acid,\textsuperscript{890} Et\(_3\)SiH with the complex BF\(_3\)–2CF\(_3\)CH\(_2\)OH,\textsuperscript{481} and cyclohexane in the presence of triflic acid–SbF\(_5\) (Scheme 5.93)\textsuperscript{298} are capable of transforming the carbonyl group to methylene group. The mechanism depicted for the reduction of maleimide is interpreted by the potential involvement of the superelectrophilic dicationic intermediates. Phthalimide is reduced similarly both with triflic acid–SbF\(_5\) and in the presence of an excess of AlCl\(_3\) at elevated temperature. Aromatics (acenaphthylene, anthracene, benz[a]anthracene, dibenz[a,h]anthracene) can also be reduced with Et\(_3\)SiH–BF\(_3\)–2CF\(_3\)CH\(_2\)OH.\textsuperscript{481}
Esterifications do not require superacid catalysis. However, various Nafion preparations have been tested in ester formation. In fact, Olah et al. showed in 1978 that Nafion-H offers a convenient and improved method for direct esterification with unchanged catalytic activity for prolonged periods of operation. Recently, esterification of cyclic alkenes and dienes with saturated and unsaturated carboxylic acids have been reported. Nafion nanocomposites exhibited activities about two orders of magnitude higher than Amberlyst 15 and gave the product esters with higher selectivities. Silica with anchored perfluorinated sulfonic acid sites (catalyst 49, Figure 5.15) showed high activity for the esterification of long-chain fatty acids with ethanol and long-chain alcohols. Nafion preparations have also been tested in transesterification of triacetin (1,2,3-triacetoxypropane) in connection with biodiesel production. In a comparative study, Nafion SAC-13, and zeolite Hβ exhibited the same activity in gas-phase esterification of acetic acid with methanol when calculated on a weight basis. On a rate-per-active sites basis, however, all catalysts including sulfated and tungstated zirconia showed similar activities. On the basis of rate data acquired on Nafion SAC-13, they concluded that the reaction occurs between acetic acid adsorbed on active sites and alcohol from the bulk phase. Nafion SAC-13 has recently been found by Meunier and Ni to be a promising candidate to esterify free fatty acids found in vegetable oils, thereby obtaining fatty-acid free oil. SAC-13 does not show mass transport limitations and can be used in batch and fixed-bed reactors, and its mild poisoning by water is reversible.

Carr and Whittaker studied lactone formation of 1-hydroxycycloalkanecarboxylic acids in superacidic media. When 1-hydroxycyclohexanecarboxylic acid was treated in HSO₃F, the protonated acid observed by ¹H and ¹³C NMR spectroscopy at −78°C slowly transformed to 1,4-lactone. When the 2,2,6,6-tetratedutero derivative was treated under identical conditions, lactone formation was not detected. This was interpreted as indicating that the intermediate dication is transformed to dication through 1,2-hydride shifts and the presence of deuterium hinders the hydride shifts. The surprising feature of the transformation is that the cyclohexyl cation does not undergo ring contraction even though cyclization requires the flipping of the chair form of cyclohexane to the boat conformation having a high energy barrier. Ring contraction of 1-hydroxycycloheptanecarboxylic acid, in turn, did take place to yield 1-methylcyclohexanecarboxylic acid 1,4-lactone as the major product. Triflic acid has been reported to be highly active and selective in the transformation of unsaturated carboxylic acids to lactones.

\[\text{HOOC} \quad \overset{\text{HSO}_3\text{F} \rightarrow \text{SO}_3\text{F}}{\text{CH}_2\text{Cl}_2, -78 \text{ to } 0\text{°C, overnight}} \quad \overset{\text{H}_2\text{O}}{\text{quench}} \quad \text{H}_3\text{C} = \overset{\text{HO}}{\text{C}} = \overset{\text{O}}{\text{C}} \text{OH} \quad \overset{1.2 \text{H}}{\longrightarrow} \quad \text{H}_3\text{C} = \overset{\text{HO}}{\text{C}} = \overset{\text{O}}{\text{C}} \text{OH} \quad \overset{\text{273}}{\longrightarrow} \quad \text{274} \quad \overset{\text{275}}{\longrightarrow} \quad \text{(5.326)}}
Triflic acid has been used in the selective esterification (O-acylation) of a series of aminoalcohols in the presence of a crown ether (DB24C8) to prepare rotaxanes.\(^{900}\) The test reaction of diethanolamine with bulky anhydride, crown ether, and triflic acid (molar ratio = 1:2:2:1.5) gave the rotaxane \(276\) in high yield in a clean reaction [Eq. (5.327)]. \(N\)-Arylmethylaminoalcohols were similarly transformed (85–92% yields).

\[
\text{HO-NH-COOH} + (\text{ArCO})_2\text{O} + \text{DB24C8} \\
\text{Ar = 3,5-dimethylphenyl}
\]

\(276\) 84% yield

Olah, Prakash, and co-workers\(^{901}\) have studied ester cleavage in superacidic media. Protonated methyl acetate was found to undergo slow acyl–oxygen cleavage in \(\text{HSO}_3\text{F–SbF}_5–\text{SO}_2\) solution even at \(-78^\circ\text{C}\) to give acetyl cation and methylloxonium ion. Diprotonation of methyl acetate to form the distonic dication \(277\) was found to be a thermodynamically favorable process by \textit{ab initio} calculations [MP4(SDTQ)/6-31G*/MP2/6-31G* level of theory], which allowed the authors to suggest a new mechanism for the acid-catalyzed ester cleavage in superacidic media [Eq. (5.328)].

\[

\]

\(277\)

5.20. ADDITIONS

5.20.1. Cycloadditions

Olah et al.\(^{902}\) demonstrated in 1979 that Nafion-H is able to catalyze Diels–Alder reaction of anthracene with a number of dienophile (maleic anhydride [Eq. (5.329)], \textit{para}-benzoquinone, dimethyl maleate, dimethyl fumarate) in chloroform or benzene
as solvent to afford the corresponding adducts in excellent yields (87–95%). In addition, reactive dienes such as isoprene, 2,3-dimethylbutadiene, and 1,3-cyclohexadiene reacted with benzoquinone, naphthoquinone, and acrolein, respectively, at room temperature without polymerization (80–93% yields). Nafion-H proved to be an excellent catalyst in the Diels–Alder reaction of olefinic acetals to provide cycloadducts in good to excellent yields and with high *endo* selectivities [Eq. (5.330)].

\[
\text{CF}_3\text{SO}_3\text{H} + \text{Nafion-H} \xrightarrow{\text{CH}_2\text{Cl}_2, \text{RT}} \text{R = Me, 10 h} \quad 81 \quad 85/15 \quad \text{R = Ph, 12 h} \quad 84 \quad 90/10
\]

The aza-Diels–Alder reaction in Eq. (5.331) catalyzed by triflic acid has been carried out to synthesize adduct 278a, an intermediate in the total synthesis of microfungal alkaloid (±)-lapatin. Whereas the reaction of the substituted azadienes led to the exclusive formation of *exo* compounds, the unsubstituted parent compound gave a 1:1 mixture of the isomers.
Gorman and Gassman\textsuperscript{905} have shown that undecatetraenes undergo cyclization (intramolecular Diels–Alder reaction) in the presence of triflic acid to provide bicyclo[4.3.0]nonyl [Eq. (5.332)], bicyclo[4.4.0]decyl, and bicyclo[5.4.0]undecyl [Eq. (5.333)] ring systems, depending on the methyl-substitution pattern. On the basis of a comparative study with varied tetraenes, they concluded that product formation, at least in some cases, could be best interpreted by a stepwise process.\textsuperscript{905,906}

\[ + \overset{\text{CF}_3\text{SO}_3\text{H}}{\text{CH}_2\text{Cl}_2, 23^\circ\text{C, 2 min}} \begin{array}{c}
\text{86\% yield} \\
\end{array} \]

(5.332)

Recently, Shin and co-workers\textsuperscript{907} have studied the cyclization of the trienol 279 and isolated two compounds (280 and 281) (Scheme 5.94). Temperature-dependence studies and the transformation of related compounds resulted in the conclusion that both a concerted process (route \(a\)) and a stepwise mechanism are operative (route \(b\)).

The formation of polysubstituted cycloheptadienones depicted in Eq. (5.334) constitutes the first example of an acid-induced ketene–diene cycloaddition.\textsuperscript{908}

\[ \overset{\text{ArCMeCO}}{\text{Ar = 4-MeC}_6\text{H}_4} + \overset{\text{CF}_3\text{SO}_3\text{H}}{\text{CH}_3\text{CN, 0\^\circ\text{C, 5 min}}} \begin{array}{c}

45\% \text{ yield} \\
\end{array} \]

(5.334)
5.20.2. Other Additions

Kotsuki et al.\textsuperscript{909} have developed a method to effect the Michael addition of \(\beta\)-ketoesters with ethyl acrylate in the presence of triflic acid under solvent-free conditions [Eq. (5.335)]. Nonactivated cyclohexanones as Michael donors and \(\alpha,\beta\)-unsaturated ketones as acceptors are also reactive. The use of menthyl acrylates did not result in any significant asymmetric induction.

n = 3-5
\]

Scheme 5.94

The addition of phenols [Eq. (5.336)], carboxylic acids, and sulfonamides [Eq. (5.337)] to alkenes can be induced by triflic acid.\textsuperscript{910,911} Whereas the yields are low with the use of 10–15 mol\% of acid, triflic acid in catalytic amounts (1–5 mol%) allow the isolation of addition products in good to high yields.
Amino-sulfonation of alkenes has been performed in a three-component reaction with $\text{SO}_3$–dimethylformamide complex ($\text{SO}_3$·DMF) and acetonitrile followed by hydrolysis.$^{912}$ Whereas amino-sulfonation occurs without the use of triflic acid, the acid accelerates the reaction considerably and prevents the formation of byproducts. The X-ray structure of intermediate 282 provided evidence that the addition is completely regio- and stereoselective [Eq. (5.338)].

The superacid $\text{CF}_3\text{SO}_3\text{H}^+\cdot\text{B(OSO}_2\text{CF}_3)_4^-$ was shown to catalyze the addition of allylsilanes to aldehydes and cyclohexanone to form homoallylic alcohols.$^{913}$ ($\text{CH}_2\text{Cl}_2$ solvent, room temperature, 60–95% yields). 2-Alkoxyallylboronates add
to aldehydes in the presence of triflic acid to afford $\beta,\gamma$-disubstituted $\delta$-lactones with an $\alpha$-exo-methylene group$^{914}$ [Eq. (5.339)]. Aromatic, straight-chain and cyclic aliphatic aldehydes are all suitable for allylboronation. While all reactions with Z-alkenes gave trans-lactones, the reversal of stereochemistry was observed for some of the $E$-alkenes. The suggested mechanism includes the borate intermediate 283, which is transformed to carbocation 284 (Scheme 5.95). When 284 is trapped by the ester before bond rotation, the expected cis stereoisomer is formed. In turn, bond rotation to form the favorable conformer followed by trapping by the ester group results in the trans isomer. $^{18}$O labeling studies indicated the loss of aldehyde oxygen. Additional results with respect to the chemo- and stereoselectivity of allylboronation promoted by triflic acid have been reported.$^{915,916}$

\[
\begin{align*}
\text{Scheme 5.95}
\end{align*}
\]

A highly selective synthesis of homoallylic alcohols has been reported by Tietze et al.,$^{917}$ who reacted methyl ketones, the chiral norpseudoephedrine derivative 285, and an allylsilane in the presence of a catalytic amount (0.2 mol%) of triflic acid [Eq. (5.340)]. The transformation was interpreted as an S$_{N}$2 attack of the allylsilane to the protonated mixed acetal 286. The obtained ethers were then cleaved to the final product, homoallylic alcohols.
Fluorosulfuric acid and triflic acid add stereoselectively to acetylenic acids, esters, and ketones to form vinyl sulfonates and vinyl triflates, respectively.\(^9\) Acids and esters yield the corresponding \(E\) derivatives with high selectivity [Eq. (5.341)]. In contrast, exclusive formation of the \(Z\) compounds was observed in the transformation of keto derivatives (\(R = 4\)-FC\(_6\)H\(_4\), \(R^1 = \text{Me}\)). The stereochemistry is accounted for by postulating the attack of the sulfonate anion from the sterically less hindered side of diprotonated intermediate 92 to furnish the \(E\) isomers. Accordingly, the stereoselectivity is always better for the triflate addition. Isomerization to the thermodynamically more stable \(Z\) isomers, however, was observed in prolonged reactions at increased temperature. Furthermore, compounds that are unreactive under the above conditions (methyl oct-2-ynoate, hex-3-yn-2-one, 4-phenylbut-3-yn-2-one) react in stronger acid (CF\(_3\)SO\(_3\)H – SbF\(_5\), \(H = 20\)) and give \(Z\) compounds. Acidity, consequently, also plays a key role in the isomerization process. Isomerization appears to be slow for acids and esters but fast for keto derivatives.

\[
\begin{align*}

\end{align*}
\]
The efficient azidobromination of cycloalkenes [Eq. (5.342)] and open-chain alkenes to give \( \beta \)-bromoalkyl azides with \( N \)-bromosuccinimide and azidotrimethylsilane is catalyzed by Nafion-H.\(^{919}\) Terminal alkenes and alkenes with bulky substituents do not react, whereas 2,3-trimethylbutene-2 reacts without catalysis. The stereochemistry of the process suggests the involvement of a bromonium ion intermediate.

**5.21. RITTER REACTIONS**

In addition to Ritter-type transformations already discussed in previous sections, there are additional examples of the Ritter reaction—that is, the transformation of alkenes or alcohols with nitriles to give carboxamides carried out under superacidic conditions.

Ritter reaction of the triene 287 in triflic acid, performed to accomplish the synthesis of a marine sesquiterpene, gave the product acetamide derivative via a predominant trans antiparallel addition of \( \text{H}^+ \) and acetonitrile to the endocyclic double bond\(^{920}\) [Eq. (5.343)].

\[\begin{align*}

\]

\[\text{(5.342)}\]

2-(Arylmethylene)cyclopropylmethanols have been reported to react with acetonitrile in triflic acid to give ring-enlarged \( N \)-(arylmethylidenecyclobutyl)acetamides\(^{921}\)
The suggested mechanistic pathway is a Ritter-type reaction with the involvement of the bicyclobutonium ion 288.

\[
\text{Ar} = \text{Ph}, 4-\text{MeC}_6\text{H}_4,
\text{3- and 4-FC}_6\text{H}_4, 4-\text{ClC}_6\text{H}_4,
\text{2- and 4-BrC}_6\text{H}_4,
\text{2,3-diClC}_6\text{H}_4, 2,4-di\text{ClC}_6\text{H}_4,
\]

Triflic acid has been applied in a three-component condensation of phenols or 2-naphthol, aromatic aldehydes, and alkyl nitriles to form amidoalkylphenols under mild conditions in good to high yields \(^{922}\) [Eq. (5.345)]. The reaction involves a Ritter-type step, wherein the intermediate condensation product reacts with the nitrile component.

Nafion-H has also been shown to be active in the Ritter reaction. Treatment of alcohols, such as benzyl alcohols, 1-adamantanol [Eq. (5.346)], and 2-norborneols with acetonitrile or benzonitrile in the presence of Nafion-H under forcing conditions (140–145°C, 18–48 h), affords the corresponding carboxamides in moderate to excellent yields (40–99%). \(^{652}\) Nafion-H can be reused after a simple activation (washing with deionized water and acetone followed by drying at 105°C).
Nafion beads, Nafion–SiO$_2$, and Aciplex–SiO$_2$ were tested by Okuhara and co-workers$^{923,924}$ in the Ritter reaction between 1-adamantanol and acrylonitrile [Eq. (5.347)]. Nafion SAC-13 exhibited the highest specific activity calculated by taking into account the number of acidic sites.

\[

(5.347)

5.22. POLYMERIZATION

The key initiation step in cationic polymerization of alkenes is the formation of a carbocationic intermediate, which can then react with excess monomer to start propagation. The kinetics and mechanisms of cationic polymerization and polycondensation have been studied extensively.$^{925-928}$ Kennedy and Maréchal$^{926}$ have pointed out that only cations of moderate reactivity are useful initiators, since stable ions such as areniun ions were found to be unreactive for olefin polymerization. On the other hand, energetic alkyl cations such as CH$_3$CH$_2^+$ were too reactive and gave side products.

It has been shown by Olah et al.$^{928,929}$ that cationic polymerization of alkenes can be initiated by stable alkyl or acyl cations as well as nitronium ion salts.

Trivalent carbenium ions play a key role, not only in the acid-catalyzed polymerization of alkenes [Eq. (5.348)] but also in the polycondensation of arenes ($\pi$-bonded monomers) as well as in the cationic polymerization of ethers, sulfides, and nitrogen compounds (nonbonded electron-pair donor monomers). On the other hand, penta-coordinated carbonium ions play the key role in the electrophilic reactions of $\sigma$-bonds (single bonds), including the oligocondensation of alkanes and alkenes (Section 5.1.5).

\[
\begin{align*}
\text{RF} + \text{BF}_3 & \rightarrow \text{R}^+ \text{BF}_4^- + \text{C}_2\text{H}_5\text{CH} \equiv \text{CH}_2 & \rightarrow \text{C}_2\text{H}_5\text{CH}\text{CH}_2\text{R} \text{BF}_4^- \\
\text{C}_2\text{H}_5\text{CH}_2 & \underbrace{[\text{CH}_2\text{R}]}_{n} \rightarrow \text{C}_2\text{H}_5\text{CH}_2[\text{CH}_2\text{R} \equiv \text{CH}_2\text{C}_2\text{H}_5 \text{BF}_4^-} \\
\text{C}_2\text{H}_5\text{CH}_2 & \underbrace{[\text{CH}_2\text{R}]}_{n} \rightarrow \text{C}_2\text{H}_5\text{CH}_2[\text{CH}_2\text{R} \equiv \text{CH}_2\text{C}_2\text{H}_5] + \text{HF} \text{BF}_3
\end{align*}
\]

(5.348)
In general, the cationic polymerization of olefins should be considered as a typical example of general carbocationic reactivity in electrophilic reactions, and all other suggested mechanisms can be looked upon as only differing in the nature of the initial electrophiles, always leading to the key trivalent alkyl cation, which then initiates the polymerization reaction [Eq. (5.349)].

\[
\begin{align*}
\text{CH}_3 & \quad \text{C} \equiv \text{CH}_2 & E^+ & \quad \text{CH}_3 \\
\text{CH}_3 & \quad \text{C} \equiv \text{CH}_2 & & \quad \text{CH}_3 \\
& & \text{alkene} & \quad \text{polymer}
\end{align*}
\]

The solid superacid Nafion-H is also a good polymerization catalyst. Isobutylene has been polymerized with Nafion-H. At 145°C, only oligomers (dimers and tetramers) were obtained; decreasing the temperature increased the molecular weight of the oligomers. The oligomerization reaction has also been studied for higher alkenes. For example, in the liquid phase, the addition of 1% by weight Nafion-H to 1-decene at 150°C gave, after 5 h, a 65% conversion to oligomeric products, of which 55% consisted of the trimer. Under similar conditions, 5-decene was converted to a 4:1 mixture of dimers and trimers, which was hydrogenated to a lubricating-type oil.

Nafion-H has also been used as a catalyst for the oligomerization of styrene. The reaction was studied by Higashimura and co-workers. Hydroxy-terminated poly(alkylene)oxides were prepared by condensation–polymerization of 1,8-octanediol and 1,10-decanediol in the presence of Nafion-H. It showed higher activity than sulfuric acid; consequently, polymerization could be carried out at lower temperature.

In the patent literature, there are several reports of the cationic polymerization of tetrahydrofuran (THF) with Nafion-H. In most cases, small amounts of acetic anhydride were added so the initial polymer had a terminal acetate group that could be hydrolyzed to the free hydroxyl. THF has also been homopolymerized and copolymerized with ethylene oxide and propylene oxide in the presence of Nafion-H.

Triflic acid has become a widely applied catalyst in various polymerization processes, and a few selected characteristic examples are discussed here. Additional basic information, examples of practical significance, and recent trends of cationic polymerization can be found in books and monographs.

A polyaldolic condensation of acetone can be induced by triflic acid to give a solid resin with a polyenic structure resembling poly(methylacetylene) having some functional groups (289).
Zolotukhin and co-workers\textsuperscript{947} have performed experimental and theoretical studies with respect to the use of superelectrophiles generated by triflic acid in the polycondensation of carbonyl compounds such as isatins,\textsuperscript{948} fluorinated ketones,\textsuperscript{949,950} and acenaphthenequinone\textsuperscript{951} with aromatics (biphenyl, diphenyl ether, 4,4'-diphenoxycacetophenone, etc.) (Scheme 5.96). It has been concluded in recent studies (PBE0/aug-cc-PVTZ//PBE0/6-31+G* level of theory)\textsuperscript{255,952} that C,O and O,O diprotonated species derived from molecules with electron-withdrawing or moderately electron-donating substituents (for example, hexafluoroacetone) do not participate in polycondensation. This is due to the high positive Gibbs energy for their formation. Acidity dependence is accounted for by a multistep mechanism involving only monoprotonated species. Monoprotonated species of molecules with strongly electron-donating substituents (for example, acetophenone), in turn, are highly stable, and their transformation is thermodynamically unfavorable.

\begin{center}
\[ \text{Scheme 5.96} \]
\end{center}

Ring-opening polymerizations can also be induced by triflic acid. It is often used for the initiation of the ring-opening polymerization of oxacycloalkanes,\textsuperscript{953,954} dioxacycloalkanes,\textsuperscript{955,956} and cyclosiloxanes.\textsuperscript{957–961} There has been a growing interest in poly(hydroxyalkanoates) and, in particular, polylactides as biodegradable and biocompatible polymers. A combination of triflic acid and a protic solvent (alcohols or water) has been recently reported to initiate the cationic polymerization of lactide at room temperature.\textsuperscript{962} Polymerization was shown to occur selectively via acyl–oxygen cleavage [Eq. (5.350)]. Polymer characteristics show that triflic acid preferentially activates the monomer compared with the polymer chain. Polymerization of L-lactide resulted in the formation of a perfectly isotactic polymer, indicating that epimerization did not occur. In a similar manner, ring-opening polymerization of (R)-\(\beta\)-hydroxybutyrolactone catalyzed by triflic acid in toluene afforded chiral poly(\(\beta\)-hydroxybutyrate). The polymerization process proceeds with the retention of
configuration. The cyclic thiocarbonate 290 undergoes a ring-opening polymerization into a poly(monothio)ester with the adamantane moieties in the backbone initiated by triflic acid [Eq. (5.351)].

\end{align*}
\]

(5.350)

Polymerization of tetrahydrofuran to produce linear polyethers or cyclic oligomers is initiated by the protonation of the ring oxygen (Scheme 5.97). The formed ion then reacts with the monomer to give tertiary oxonium ion intermediates. Macrocyclic oligomer formation proceeds by intramolecular attacks involving backbiting (route a) or tailbiting mechanism (route b). The ability of triflic acid to form tertiary oxonium

\[

Scheme 5.97
ion intermediates, participating in chain growth instead of ester formation, was shown to be the highest among various initiators studied (CF₃SO₂H > HSO₃F > MeOTf >> ScOF). The highest concentration of crown ethers ranging from 15-crown-3 to 100-crown-20 [(C₄H₈)n, n = 3–20] was generated in nitromethane.

Kanoh et al.⁹⁶⁶ have reported unusual monomer isomerization–polymerization processes of oxetanes with varied substituents. Cyclic imide-substituted monomers, such as 170, undergo isomerization catalyzed by triflic acid as shown previously in Eq. (5.266) and then polymerize. Polyacetals 291 are formed below room temperature (single ring opening), whereas at elevated temperature (120–130°C) polyethers 292 are isolated (double ring-opening). Oxetanes with ester substituents exhibit similar dual characteristics.⁹⁶⁷ Monomer 170, however, showed an exceptional behavior yielding the oligoindene derivative 293 with a carbon backbone.⁹⁶⁸

Hyperbranched carbohydrate polymers have been synthesized through ring-opening multibranching polymerization of 1,4-anhydroerythritol and 1,4-anhydro-L-threitol using triflic acid and fluorosulfuric acid as cationic initiators.⁹⁶⁹ HSO₃F resulted in a polymer of lower molecular weight. The proposed mechanism shown for 1,4-anhydroerythritol includes ring opening with the protonated monomer initiator, and branching is induced by proton transfer reaction (Scheme 5.98).

Photoinitiated cationic polymerization is in widespread use in UV curing and photoresist technology. Crivello and Lam⁹⁷⁰ were the first to report that diaryliodonium salts undergo photodecomposition to generate Brønsted superacids (Scheme 5.99), which are capable of initiating the polymerization of suitable monomers. Since then, triarylsulfonium and triarylphosphonium and other salts with weakly coordinating anions have also been applied.⁹⁷¹,⁹⁷²

A rare example of cationic polymerization of emulsified epoxy resins has been reported by Walker et al.⁹⁷³ Polymerization of water emulsion of epoxy resins with a variety of superacids (triflic acid, HClO₄, HBF₄, HPF₆) results in polyols with two glycidyl units (294) in contrast to commercial epoxy resins with one unit separating the aromatic moieties. The level of residual glycidyl ether and Bisphenol-A units is also much lower than in conventional epoxy resins.
Lacaze and co-workers\textsuperscript{974} have prepared poly(\textit{para}-phenylene) films by electropolymerization of benzene in strong acidic media including triflic acid and
fluorosulfuric acid. The films grown in superacids are characterized by sharp redox peaks in contrast to films prepared in other acids, which exhibit wide, ill-defined peaks. Poly(\textit{para}-phenylene) prepared in the superacid media has linear chains, a high degree of polymerization, and a narrow molecular weight distribution. Extremely well-organized polymers were prepared by performing the electropolymerization in SO$_2$ or in organic solvents.$^9_{75}$

Jones and co-workers$^9_{76}$ have recently reported the use of catalyst 49 (Figure 5.15) with perfluorinated alkanesulfonic acid sites anchored to SBA-15 as a methylaluminoxane-free supported cocatalyst for ethylene polymerization. When catalyst 49 and trimethylaluminum were used in combination with Cp*$_2$ZrMe$_2$ as the metallocene precatalyst, productivities as high as 1000 kg polyethylene mol Zr$^{-1}$ h$^{-1}$ were obtained without experiencing reactor fouling.

In a recent communication, a microsystem allowing controlled polymerization and block copolymerization of vinyl ethers with triflic acid as the initiator at $-25^\circ$C has been described.$^9_{77}$ The system allows a high level of control on molecular weight distribution.

### 5.23. MISCELLANEOUS REACTIONS

Isomerization of 3,3'- and 4,4'-dimethylbiphenyl in triflic acid results in the formation of only 3 of the possible isomers: 3,3'-dimethylbiphenyl (~40%), 3,4'-dimethylbiphenyl (~55%), and 4,4'-dimethylbiphenyl (~5%).$^9_{78}$ This product composition reflects the relative stability of the intermediate carbocations. Isomerization was suggested to occur by ipso protonation to the methyl group followed by a slow methyl migration as the rate-determining step [Eq. (5.352)]. The intermediate formed by ipso protonation to the phenyl group was calculated to have higher energy by 5.4 kcal mol$^{-1}$ (AM1 method).

\]

Triflic acid has proved to be an efficient catalyst to promote direct C-alkylation of 1,3-dicarbonyl compounds with benzyl alcohols$^9_{79}$ [Eq. (5.353)]. Alkylation of
hydroquinone by tert-butyl alcohol in a solventless reaction yields 2,5-di-tert-butylhydroquinone (93% selectivity at 90% conversion, 150°C), whereas 2-tert-butylhydroquinone is the main product in 1,4-dioxane (79.5% selectivity at 39% conversion).\(^980\)

\]

Aubé and co-workers\(^981,982\) have found that enolizable ketones react with benzyl azide in triflic acid to yield \(N\)-(phenylamino)-methylated products [Eq. (5.354)]. The transformation is an aza-Mannich reaction interpreted with the involvement of the Mannich reagent \(N\)-phenyl iminium ion 295 formed \textit{in situ} in a Schmidt rearrangement. Cyclic tertiary alcohols react with alkyl azides in triflic acid to yield \(N\)-alkylamines (296, 297)\(^983\) [Eq. (5.355)]. The Schmidt rearrangement was used to transform Merrifield resin into amino-polystyrene resin by reacting the azido derivative in excess triflic acid (\(\text{CH}_2\text{Cl}_2, 0^\circ\text{C}\)).\(^984\)

N-Alkylation of methyl \(N\)-(trimethylsilyl)pyroglutamate with benzhydryl chlorides or trimethylsilyl benzhydryl ethers can be carried out in almost quantitative yields with the use of catalytic amounts of triflic acid (0.3–3 mol\%)\(^{985}\) [Eq. (5.356)].

\(\text{(5.357)}\)

\(\alpha\)-Hydroxy ketones have been shown by Olah and Wu\(^{987}\) to undergo various transformations in triflic acid depending on their substitution pattern. Compounds without \(\beta\)-hydrogen give fragmentative products (Scheme 5.100, route \(a\)). Since formation of the intermediate carbocation is not favored because of the lack of stabilizing substituents, a concerted mechanism was suggested. A similar mechanism accounts for the exclusive formation of \(\alpha,\beta\)-unsaturated ketones under similar conditions (Scheme 5.100, route \(b\)). The involvement of the stable benzylic cation, in turn, allows the formation of the cyclized product as shown in route \(c\).

In the 1980s, Rudenko et al.\(^{988,989}\) made pioneering studies on the electrochemical oxidation of various aromatic compounds in HSO\(_3\)F and HSO\(_3\)F–SbF\(_5\). Recently,
Oxidations using the \( \text{HSO}_3\text{F} - \text{PbO}_2 \) system have been reported in a long series of papers. The studies, among others, included the oxidation of substituted nitrobenzenes and anilines, benzoic acids, phenols and derivatives, and so on, in the temperature range \(-75^\circ\text{C}\) to \(0^\circ\text{C}\). Product formation is interpreted by two one-electron oxidation steps followed by a proton loss. The formed intermediate reacts with the fluorosulfate anion and the work-up procedure leads to the final chlorosubstituted product as shown for 2-methylbenzonitrile [Eq. (5.358)]. In most cases, a range of products including various dimers are formed usually in low yields, but selective transformations may also be observed. Oxidation of 2,4,6-trisubstituted benzonitriles, for example, affords carboxamides in high yields formed in a Ritter-type transformation [Eq. (5.359)]. Benzonitriles could be transformed into 2,4,6-triaryltriazines (298) in \( \text{HSO}_3\text{F} \) alone at higher temperatures (20°C, 3 h, 49–65% yield). The elementary steps, the nature of the reaction intermediates, and general trends of chemical and electrochemical oxidation of aromatics in \( \text{HSO}_3\text{F} \) have been discussed in a review paper.

\end{align*}
\] (5.358)
Harmer and co-workers tested various Nafion-based samples in the dimerization of α-methylstyrene to form isomeric pentenes and a cyclic dimer, which are of industrial interest: 13% and 40% Nafion–silica nanocomposites exhibited near-complete conversion and gave the cyclic dimer with high selectivity [Eq. (5.360)], whereas compound was the main product over Nafion NR50. In sharp contrast, isomeric pentenes could be obtained in a continuous process (86% selectivity at conversion >95%). Similar findings were reported with Nafion immobilized in MCM-41 mesoporous silica. In kinetic studies, 13% Nafion–silica and the catalyst with anchored perfluorinated sulfonic acid site (catalyst 48, Figure 5.15) showed the highest activity. Dimerization of isobutylene has been studied in a forced-flow catalytic membrane reactor using Nafion-based catalytic membranes made with various binders. The best results were found for Nafion SAC-13 exhibiting high selectivity (80%) at low conversion (45%). The fast removal of product isooctene inhibits secondary processes, whereas byproducts are purged from the active sites, thereby preventing catalyst deactivation.
Olah and Ip\textsuperscript{999} showed that Nafion-H catalyzes condensation of acetone to give mesitylene\textsuperscript{999} [Eq. (5.361)]. In contrast to phosphoric acid and sulfuric acid, the reaction carried out in a flow system gives the product with high selectivity. Likewise, substituted aryl methyl ketones can be transformed to 1,3,5-triarylbenzenes\textsuperscript{1000} [Eq. (5.361)]. \textit{ortho}-Substituted acetophenones, however, do not react.

In the first edition of this book we wrote the following:

“Acids have played a fundamental role in the entire history of chemistry. Mineral acids such as sulfuric and perchloric acid were until recently considered as the strongest acids. In the last two decades, emergence of acid systems up to $10^{15}$ times stronger than 100% sulfuric acid has opened up a whole new area of chemistry. These superacids, reviewed in the present monograph in a systematic way, range from liquid systems such as antimony pentafluoride–hydrogen fluoride, antimony pentafluoride–trifluoromethanesulfonic acid, and related acids containing arsenic, tantalum, and niobium pentafluorides and the like, to solid superacids such as polymeric perfluorinated resinsulfonic acids (Nafion-H), immobilized or intercalated antimony pentafluoride and related Lewis acid-based systems. The exceedingly high acidity of these systems covering a broad range allows many weak bases to undergo acid-catalyzed reactions, which otherwise would not take place using conventional acid catalysts. Many hydrocarbon conversions, including those of methane and alkanes, are some of the examples of applications catalyzed by superacids that in the future are expected to gain increasing importance. Usually, acid-catalyzed reactions such as isomerization of alkanes, carried out with mineral acids or conventional Friedel–Crafts systems, necessitate relatively high temperatures. However, superacids promote such reactions at much lower temperatures, thus allowing favorable isomer distribution of branched hydrocarbons (increasing the octane number significantly).

A whole array of potential weakly basic reagents, such as CO$_2$, CO, O$_3$, O$_2$ (singlet), N$_2$O, Cl$_2$, Br$_2$, and the like, are starting to show electrophilic reactivity under superacid-catalyzed conditions. These reactions could lead to novel and practical applications, and some of them are already emerging. Ionic reactions generally show much higher selectivity than their free radical counterparts. The ability of superacid catalysts to cleave carbon–carbon bonds with ease has resulted in novel hydrocarbon cracking applications, particularly in systems where metal-based catalysts are susceptible to deactivation (poisoning) by impurities such as sulfur and nitrogen compounds. This is of particular interest in processing heavy oils, tar sands, and oil shale, as well as in coal conversion–liquefaction processes.
Superacid-catalyzed reactions and ionic reagents (obtained under superacidic, stable ion conditions) are gaining increasing significance in synthetic and natural product chemistry, and this trend is expected to continue and expand. Some special applications, such as use of intercalated antimony or arsenic pentafluoride/graphite (or polyacetylene) as highly conducting (even superconducting) materials, has attracted and will continue to attract considerable attention.

Future development of new and improved superacidic systems, particularly allowing long onstream time in catalytic applications without deactivation and ease of regeneration, is of particular interest. Applications of superacids are foreseen to expand in catalysis and in synthetic chemistry, as well as in preparation and study of reactive ionic intermediates.”

It is rewarding to see that many of our expectations have materialized during the last two decades. The use of superacids has become common practice in synthetic organic chemistry as demonstrated by the numerous new areas of applications, including particularly their use in the chemistry of hydrocarbons, protecting groups, heterocycles, and carbohydrates. Furthermore, superacids have also found wide application in the generation of varied inorganic cations and complexes. Additional important developments include that of new weakly coordinating anions and methods to manufacture and use Nafion–silica and other nanocomposites, which show high stability and specific activities in catalytic applications.

Extending the concept of superacids to varied superelectrophiles has emerged as a productive new field in recent years (G. A. Olah and D. A. Klumpp, Superelectrophiles and Their Chemistry, Wiley-Interscience, Hoboken, NJ, 2008). Highly reactive and activated protosolvated or multiply charged superelectrophilic intermediates are involved in varied chemical reactions, many of them of substantial practical significance.

definition of, 1
determination, 4, 5, 8
gas-phase, 22
of Lewis acids, 23, 24, 25, 26
of Magic Acid, 49, 50, 51
ranges of superacids, 7, 9
Acidity (Continued)
relative, 21
role in
electrochemical oxidation, 521, 522
solubility of alkanes, 524
Acidity-dependence studies, 606, 698, 741
in alkylation with TiOH–TFA, 551, 582, 583
in cyclodehydration with TiOH–TFA, 596, 597, 598, 604
in formation of benzoazines, 691
in formylation, 629
in isomerization of pivalaldehyde, 725
Acidity functions, 4
$H_R (J_0)$, 5, 20
Acidity increase, 7
Acidity measurement
by chemical kinetics, 20
by electrochemical methods, 20
by heats of protonation, 22
of Lewis acids, 23, 24
by line-shape analysis, 18, 19
by NMR
chemical shift, 15, 27
rate exchange, 14
for solid acids, 27
by spectrophotometry, 11
Acid soluble oils, in alkylation, 550
Aciplex, perfluorinated polymer resin acid, 67
Aciplex–SiO$_2$, 67
in alkylation, 584, 585
in Ritter reaction, 744
Acrolein, Diels–Alder reaction of, 736
Acrylonitrile, in Ritter reaction, 744
Activated complex, of methane exchange, 507, 508
Acyclic ions, hydrogen-bridged, 247
Acylals, see 1,1-Diacetates
Acylation
of alkylbenzenes, 608
intramolecular, 611, 612, 614
Acyl cations, 175, 179, 188, 616
as initiators, in cationic polymerization, 744
in Koch–Haaf reaction, 618
Acyl chlorides, acylation with, 609, 614
$N$-Acyl enaminoketones, cyclialkylation of, 604
Acyl fluoride–boron trifluoride complexes, 84
$N$-Acyliminium ions
cyclialkylation of, 605
in situ preparation and ring closure of, 605
Acylim ions, 188, 190, 191, 621
Acylim salts, in aza-Nazarov cyclization, 606
Acyl–oxygen cleavage
in ester cleavage, 735
in polymerization of lactide, 746, 747
Acyl trifluoroacetates, as acylating agents, 610
Adamantane
alkylation of, with alkenes, 548, 553
$\sigma$-alkylation of, 548
formation of, 535
formylation of, 631
ionic fluorination of, 644
monochlorination of, 650
monoiiodination of, 651
nitration of, 637
oxygenation of, 676
Ritter-type reaction of, 644
1-Adamantane carboxaldehyde, synthesis of, 631
Adamantane dication(s), calculated structures of, 150, 151
Adamantane-2,6-diyl dications, 150, 151
1-Adamantanol, in Ritter reaction, 743, 744
Adamantanone, ionic hydrogenation of, 728
1-Adamantanoyl chloride, adamantylation with, 571
Adamantonium ions, calculated structures of, 224
Adamantylation of aromatics, 567, 570–574
$para$-Adamantylation of arenes, 574
Adamantyl cation(s), 117–119, 257, 571, 573
in alkylation, 553
$^1$H NMR spectrum of, 117
methyl-substituted, 118
stability of, 119
Adamantylideneadamantane, halonium complexes, 373, 374
X-ray studies, 374
Adamantylideneadamantyl alcohols, protonation of, 680
Adamantylidene cations, 124, 125
AgBF$_4$, 87, 186, 240, 323, 327, 330, 336, 352

$[\text{Ag(CO)}]^+[\text{B(OTeF}_5\text{)}_4]$ salt, 456

$[\text{Ag(CO)}_2]^+[\text{B(OTeF}_5\text{)}_4]$ salt, 456

AgSbF$_6$, 87, 195, 323, 356, 363, 364, 447

in chlorination and chlorolysis, 648, 649

AlBr$_3$

in alkylation of aromatics, 592

intercalated into graphite, 74

in ionic hydrogenation, 729, 732

AlBr$_3$–Br$_2$, intercalated into graphite, 74

AlBr$_3$–graphite intercalate, 74

in gas-phase alkylation of aromatics, 557

in transethylation of aromatics, 587, 588

AlBr$_3$–HBr

in alkylation of aromatics, 592

in cyclialkylation, 607

AlCl$_3$, 442. See also Aluminum chloride

in acylation, 609

in alkylation of aromatics, 558, 568, 569, 573, 592

complexed with Lewis acids, 70

complexed with polymeric resin sulfonic acids, 65

fluorinated, 74

in forming oxazolines, 692

in formylation, 628

in generating fullerene cations, 165, 166

intercalated into graphite, 74

in ionic hydrogenation, 729–733

Al$_2$Cl$_6$, in chlorination and chlorolysis, 648

Al$_2$Cl$_6$/Al, in carboxylation, 627

AlCl$_3$–graphite intercalate, 74

in alkylation of aromatics, 557, 566, 568, 569

in transethylation of aromatics, 557, 587, 588

AlCl$_3$–HCl

in alkylation of aromatics, 592

in disproportionation, 587

AlCl$_3$–metal chlorides, 71

AlCl$_3$–metal sulfates, 70

AlCl$_3$–NiO–SiO$_2$, in ethylation of ethylbenzene, 558

Alcohol(s)

acetylation of, 678

acylation of, 677

alkylation with, 560, 561, 563, 564

benzylic, ionic hydrogenation of, 733

carbonylation of, 619, 620

dehydration of, 699, 700

temperature dependence, 699

electrophilic oxygenation of, 185

heat of ionization, 92

hydrofluorination of, 655

ionic hydrogenation of, 733

ionization of, 5, 141

long-chain, esterification with, 734

protonation of, 108, 109

tertiary, ionic hydrogenation of, 733

THP ethers of, 677–679

trimethylsilylation of, 677, 679

unsaturated

carbonyl–ene cyclization of, 725

cyclization of, 680

Aldehydes

in additions, 739, 740

protection of, 677

protonated, resonance forms of, 173

Aldimines, chiral, in forming Mannich-type products, 752

Aliphatic alcohols

protonated, reactivity of, 315

protonation of, 313, 314

Aliphatic ethers, protonation of, 110

Aliphatic glycols

protonated, reactivity of, 315–317

protonation of, 315

Aliphatic thiols, protonation of, 332

Alkadienyl cations, 125

Alkaloids, 736

cyclization of, 681, 689, 690, 732

fluorination of, 652–654

ionic hydrogenation of, 732

oxygenation of, 666

Alkanes, see also Saturated hydrocarbons

as acylating agents, 616, 617

in alkylation and acylation, 617, 618

alkylation of, 543, 553

theoretical study, 550

chlorination of, 647, 648

chlorolysis of, 647

electrochemical oxidation of, in strong acids, 520–524

electrophilic oxygenation of, 185

fluorination of, 648–651

ionization of
Alkanes (Continued)
oxidative pathway, 511, 516
over strong solid acids, 516
in superacids, 510
in weaker superacids, 517
isomerization of, 524
in CF₃SO₃H, 529
over solid superacids, 531
monobromination of, 651
nitration of, 636, 637
nitrolysis of, 637
oxygenation of branched-chain, 661, 662, 668
straight-chain, 663, 670
polycondensation of, 553
protonolysis of, 503
prototated, 206
anodic oxidation of, 520
protonation of, 503
redox couples, standard potential of, 523
solubility of, 524
tertiary, ease of oxidation, 523
3-Alkenamides, in ring closing, 683
Alkene(s)
in addition, 738, 739
amino-sulfonation of, 739
azidobromination of, 742
bis-hydroxylation of, 673
bridgehead, protonation of, 250
bromofluorination of, 655
carboxylation of, 619
cationic polymerization of, 744, 745
electrochemical oxidation of, 524
hydrofluorination of, 655
as initiators, in alkane isomerization, 529
nitration of, 640
protonation of, 108
reversible deprotonation of, 516
Alkenoyl cations
diprotonation of, calculations, 191
resonance contributions of, 191
Alkenylamines, N-protected,
hydroaminatons of, 685
Alkenyl(aryl)iodonium ions, 368, 369
Alkenylation, 594
Alkenyl cations, 123, 530
Alkenydselenonium ions, 353
Alkonium ions, 206
2-Alkoxyallylboronates, addition of, 739, 740
Alkoxycarbenium cations, 181, 187
X-ray studies, 188
Alkoxy group
role of, in ester cleavage, 176
surface-bound, 519
Alkoxymethyl cations, fluorinated, 187
Alkoxysulfonium perchlorates, X-ray studies, 344
Alkyde shift, 525, 535
Alkylaminodiaczonium ions, 388
9-Alkylanthracenes, protonation of, 130
Alkyl aryl ethers
cleavage of, 589
protonation of, 322, 655
rearrangement of, to ring-alkylated phenols, 589
Alkyl azides, in aza-Mannich reaction, 751
2-Alkyl-N-benzylidenes, cyclialkylation of, 604
Alkyl cations, as initiators, in cationic polymerization, 744
Alkyl chloroformates, alkylation with, 585, 586
Alkyl groups, effect on disproportionation, 587
Alkylaryl methyl cations, 140, 145
Alkylated intermediate, 580
Alkylation, 502, 503, 523
of alkanes, 543
of alkenes, in cracking, 540, 541
with alkylcarbenium hexafluoroantimonates, 589
of aromatic hydrocarbons, 554
competition with hydride transfer, 545, 546
of ethers, 323–325
intramolecular, 595, 596
of selenides, 352
of sulfides, 335, 336
of tellurides, 353
N-Alkylation, 752
Alkylation–acylation sequence, 613
Alkylation and acylation, one-step, 617, 618
Alkyl azides, protonation of, 388
Alkylazulenes, protonation of, 160
Alkylbenzenes
formylation of, 629
isomerization and transalkylation of, 586
Alkylbenzenes (Continued)  
monohydroxylation of, 663, 664  
sulfonation of, 634  

Alkylcarbenium hexafluoroantimonates,  
alkylation with, 589  

Alkylcarbenium ions, in oxygenation, 669  

Alkylcarboxonium cations, 181, 186  

Alkyl cations, 93  
$^{13}$C NMR shifts of, 97, 98  
coupling constants of, 99, 100  
early studies, 93  
electronic spectra of, 104  
$^1$H NMR parameters of, 96  
IR frequencies of, 104, 105  
Raman frequencies of, 104, 105  
Raman spectra of, 106  
reaction of, with hydrogen, 505  

Alkyl chlorides, heats of ionization of, 92  

1-Alkylcyclohexanols, acylation of, 677  

Alkylcyclopropylhalonium ions, 365  

Alkyldiaryloxonium ions, 325  

Alkyldiazonium ions, 384  

Alkyldiazonium ions, 384  

Alkylene dihalides, alkylation of, 366  

Alkylenehalonium ions  
bridged, long-lived, 362  
dialkyl, 366, 367  

Alkyl esters  
of carboxylic acids, as alkylating agents, 585  
of oxalic acid, as alkylating agents, 585  
$s$-Alkyl esters, protonation of, 192  

Alkyl fluorides  
$^1$H NMR spectra of, in SbF$_5$, 95  
in SbF$_5$, 94  

Alkyl fluorosulphonium hexafluorometalates, 335  

Alkyl halide–Lewis acid halide complexes, 84  

Alkyl halides  
alkylation of aromatics with, 566  
protonation of, 93  
self-condensation of, 362  

Alkyl hydrogen carbonates, protonated, 179, 180  

para-Alkylphenol methyl ethers,  
chlorination of, 656  

para-Alkylphenols, chlorination of, 656  

Alkylsulfonylumionium ions, 192  

Alkyl tellurides, protonation of, 351  

Alkyl thiohaloformates, fragmentative ionization of, 110, 111  

Alkylvinylhalonium ions, 365  

Alkynyl[aryl]iodonium salts, X-ray studies, 369  

Alkynylcyclopropenylium ions, 157  

1-Alkynylidiphenyloxonium tetrafluoroborates, 355  

Alkynylselenonium ions, 353  

$\alpha$-(Alkynylsiloxy)aldimines, hetero Diels–Alder reaction of, 687  

Alkynyltungsten(II) complexes, oxidative carbylation of, 626, 627  

Alkynylxenonium salts, 463  

Allenenes, protonation of, 125  

Allenylmethyl cations, 134, 135  

Allenylselenonium triflates, 353  

Allylboronation, 740  

Allyl cation(s), 116, 124, 316  

1,3-dimethyl, 316  

rotational barrier of, 124  

studies by cryogenic matrix isolation, 124  

 Allylic alcohols, bis-hydroxylation of, 673  

Allylic amines  
fluorination of, 652  
hydrofluorination of, 652  

$\pi$-Allylic cations, complexed to metal, 204  

Allyl leaving group approach, 403, 411  

Allylsilanes, in additions, 739, 740, 741  

Allyl sterols, 2-oxonia Cope rearrangement of, 725  

Alumenium ions, 400  

Alumina, chlorinated, 70, 524  

$\gamma$-Alumina, fluorinated, 74, 75  

Aluminum chloride, see also AlCl$_3$,  
in alkane isomerization, 503, 517, 524, 535  
in alkylation of benzene, 554, 555  
in ionic hydrogenation, 730, 732  

Aluminum halides, in ionic hydrogenation, 729  

Aluminum trichloride, in catalytic cracking, 539  

Amberlite IR-112, 554  

Amberlyst  
in cyclization of pseudoionone, 721  
in esterification, 734  

Amides  
phenyl-substituted, formation of 592, 593  

$O$-protonation of, 195, 196
Amidines, cationic derivatives, resonance forms of, 199
Amidoborenium ions, 398
Amidocyclopentadienyl As cation, X-ray studies, 423
Amidocyclopentadienyl Sb cation, X-ray studies, 423
(Amidomethyl)dimethylsilanols, protonated, X-ray studies, 318
Amination of aromatics, 659
Amine poly(hydrogen fluoride) complexes, in alkylation, 551
Amines, protonation of, 111
Aminoacetals, as alkylating agents, 580
Aminoalcohols, esterification of, 735
Aminodiazonium ion(s), 387
amination with, 659
diazoatization of, 389
X-ray studies, 388
Aminodiazonium tetrachloroaluminate, 659
Aminofluorosulfonium ions, 344
5-Amino-1-naphthol
as alkylating agent, 591
ionic hydrogenation of, 729
Amino-polystyrene resin, 751
Aminopropylated silica, modified with triflic acid, 71
Amino-sulfonation, 739
tert-Amyl cation, 332, 504, 542
AchimERIC assistance, 703
Androsta-4,6-diene-3,17-dione, isomerization of, 717, 718
Androsta-1,4,6-triene-3,17-dione, rearrangement of, 723, 724
α-Angelicalactone, cleavage and polymerization of, 178
1,4-Anhydroerythritol, polymerization of, 748
Anhydroketopyranoses, synthesis of, 702
1,4-Anhydro-L-threitol, polymerization of, 748
Anhydrovinblastine, difluorination of, 654
Anilides, hydroxylation of, 665
Aniline, bromination of, 656
Aniline derivatives
acylation of, 677
hydroxylation of, 665
trifluoromethylation of, 566, 567
Anilinium ion, in hydroxylation, 665
para-Anisaldehyde, protonated, as indicator, 18, 19, 322
Anisole
acylation of, 611, 614, 615
adamantylation of, para selectivity, 576
alkylation of, 564, 566, 574
bromination of, 656
formylation of, 631
rearrangement of, 589
[16]Annulene, protonation of, 162
[16]Annulenediyldication, 162
Anodic oxidation, to generate carbenium ions, 529, 553
Anthracene(s)
Diels–Alder reaction of, 735, 736
ionic hydrogenation of, 728, 733
two-electron oxidation of, 163
Anthracenium ions, 130
Antiaromaticity, 156, 157
Antihistamine precursor, in cyclodehydration, 597
Antimony pentafluoride, 42, 84. See also SbF5
hydrolysis of, 43
polymeric structure of, 43
preparation of, 43
Aprotic nitrating agent, 639
Aprotic organic superacids, 10, 46
in alkylation and acylation, 617
in carbonylation of alkanes, 624
in formylation, 631
in halogenation, 651
in isomerization, 537
Arenes
benzylation of, 579, 580
formylation of, 628
iodination of, 658
transacylated, 615
Arenesulfinyl cation, 635
Arenesulfonic acids, sulfonation with, 634
Arenesulfonyl chlorides, sulfonation with, 635
Arenium ions, 126, 129, 145, 567, 577, 579, 587, 630
para-adamantylated, in isomerization, 571, 573, 577
bis-silylated, X-ray studies, 128, 129
stabilized by Os complexation, 205
Ar$_2$H$^+$ cation, 461  
ArKH$^+$ cation, 461  
Aromadendrane alkenes, rearrangement of, 714, 715  
Aromatic aldehydes  
  hetero Diels–Alder reaction of, 683  
  multicomponent reaction of, 755  
  in Ritter reaction, 743  
  carbonyl compounds, hydroxylation of, 665  
  carboxamides, as acylating agents, 610  
  nitro compounds, as indicators, 5, 14, 37, 47, 56  
Aromatic compounds  
  bicyclic, formylation of, 629  
  carbonyl, 18  
  disproportionation of, 587  
  halogenation of, 655  
  use in industry, 502  
Aromatic cyclization, 718–720  
Aromatic ethers, demethylation of, 717, 718  
Aromatic hydrocarbons, see also Aromatics  
  acylation of, 608  
  alkylation of, 554  
    with acid derivatives, 585  
    with alcohols, 560  
    with alkenes, 554  
    with alkyl halides, 566

  thiocarboxylation of, 633  
2$\pi$-Aromatic pericyclic systems, 264  
Aromatics, see also Aromatic hydrocarbons  
  activated, nitrozation of, 644  
  amination of, 659  
  carboxylation of, with carbon dioxide, 627  
  deactivated  
    alkylation of, 576  
    iodination of, 657, 658  
    nitration of, 638, 639  
    de-tert-butylation of, 587  
    deformylation of, 616  
  electrochemical oxidation of, 752–754  
  electron-rich, alkylation of, 561, 562  
  formylation of, 627  
  halogenation of, 655  
  in polycondensation, 746  
  nitration of, 636  
  oxygenation of, 663  
  substituted, alkylation of, 565  
  sulfonylation of, 634, 635  
Aromatic silanes, desilylative acylation of, 616, 617  
Aromatic stabilization, in cations and dications, 157  
Aromatic sulfonamides, in cyclialkylation, 596  
Aromatic sulfoxides, synthesis of, 635  
Aroyl anhydrides, in acylation of aromatics, 614  
  azides, protonation of, 196  
  chlorides, in acylation of aromatics, 614  
  cyanides, protonated, 417  
Aroylation, of fluorobenzene, 610  
  with arenecarboxylic acids, 614  
[(Ar$_3$PAu)$_4$O]$^{2+}$ (BF$_4$)$^-$, X-ray studies, 329  
Arsenium cations, 423, 424  
  with donor ligands, X-ray studies, 423  
ArXe$^+$ BF$_4^-$ salts, 462  
ArXeH$^+$ cation, 461  
Aryladamantanolns, in ionic hydrogenation, 733  
Arylalkanoins, cyclialkylation of, 607  
Arylalkenes, cyclialkylation of, 607  
Arylalkyl-benzoic acids, intramolecular acylation of, 614  
Arylalkyl-benzoyl chlorides, intramolecular acylation of, 614  
Arylalkylepoxides, cyclialkylation of, 607  
Arylamines, aza-Diels–Alder reaction of, 687  
Aryldiazonium ions, 386  
  dediazoniation of, 386  
  N$_a$–N$_b$ inversion, 386  
Aryl epoxides, to give condensed aromatics, 698  
2-Arylethylamine aldimes, cyclialkylation of, 604  
3-Arylindenones  
  double protonation of, 601  
  formed in cyclodehydration, 600, 601  
Aryl ketones, cyclodehydration of, 596  
Arylmethyl cations, 140  
2-(Arylmethylene)cyclopropylmethanols,  
  Ritter reaction of, 742, 743
1,2-Aryl migration, 166
3-Aryl-2-nitropropionates, to form benzoazines, 691
2-Aryl-2-norbomyl cations, $^{13}$C NMR chemical shifts of, 236
Aryloxadonium cations, as cyclohexadienyl ions, 425
2-Aryloxybenzonitriles, intramolecular acylation of, 612
Aryloxonium cations, as cyclohexadienyl ions, 425
2-Aryloxybenzonitriles, intramolecular acylation of, 612
Aryl pinacols, to give condensed aromatics, 698
3-Arylpropyonates, as alkenylating agents, 594
N-Arylsulfonylcarbazoles, formed in cyclialkylation, 596
N-Arylsulfonylindoles, formed in cyclialkylation, 596
N-Arylsulfonylpyrroles, formed in cyclialkylation, 596
5-Aryltetrahydrofuran-2-ones, intramolecular acylation of, 613
Arylxenonium triflates, 462
AsCl$_4$ $^+$ AsF$_6^-$/C$_0$ salt, X-ray studies, 394
AsF$_5$, 44, 201, 431, 434, 439, 442, 444, 447, 451, 452
intercalated into graphite, 73
AsFCl$_3$ $^+$ AsF$_6^-$/C$_0$ salt, 394
AsH$_4$ $^+$ MF$_6^-$/$C_0$ salts, 395

2-Azaallenium ions, 202
2-Azaallyl cations, bent structure, 381, 382
1-Aza-2-azoniaallene salts, 382
cyanamidium salt of, X-ray studies, 382
Aza-Diels–Alder reaction, 687, 736
Aza-Mannich reaction, 751
Aza-Nazarov cyclization, 606
Azeotropic nitration, 643
sulfonation, 634
Azidobromination, of alkenes, 742
$\alpha$-Azidocarboxonium ions, 196
Azido compounds, in synthesis of nitrogen heterocycles, 688
Azidotrimethylsilane, in azidobromination, 742
2-Azoniaallene cations, 381
Azulenes, substituted, hydride abstraction from, 160
Azulenium cations, 159, 160
Backbiting mechanism, in ring-opening polymerization, 747
Baeyer–Villiger oxidation, 662, 673
9-Barbaralyl cation(s), 253, 262
$^{13}$C-labeled, 255
degenerate rearrangement of, sixfold, 256
equilibrating structures of, 254
isotopic perturbation, 255
NMR, temperature dependence of, 255
octadeuteriated, 255
total degeneracy of, 253, 255, 256
$\sigma$-Basicity of C–H bond, 506
of hydrocarbons, 542
of methane, 506
B(CF₃)₃, 45, 46
B(C₆F₅)₃, 45, 46
Benzaldehyde(s)
  alkylation of aromatics with, 577–579
dication intermediate, 578
Benz[a]anthracenes
  ionic hydrogenation of, 733
  protonation of, 130, 131
Benz[a]anthracenium cations, 130
Benzene
  acylation of, 609, 610, 611, 612
    competitive, 609
  adamantylation of, 567, 570–572
  alkylation and acylation of, 617, 618
  alkylation of
    with alcohols, 563, 565
    with aldehydes, 577, 578
    with alkenes, 558, 568, 569
    with alkyl halides, 567, 575
    with aminoacetalts, 580
    competitive 560, 565, 571, 572, 574
    with 1,2-dicarbonyl compounds, 582
    with diethylhalonium hexafluoroantimones, 589, 590
    with formaldehyde, 584, 585
    with heteroaromatic compounds, 581, 592, 593
    with hydroxybiindantetraone, 561
    with phenols and ethers, 593
    with substituted aromatics, 591, 592
    with 1,2,3,6-tetrahydropyridines, 556
    with unsaturated amines, 554
    with α,β-unsaturated carboxamides, 554
  benzylation of, 565
carbonylation of, 626
cyclialkylation of, 595
electrophilic hydroxylation of,
  competitive, 675
electropolymerization of, 749, 750
ethylation of, 554, 557, 558
formylation of, 627, 628
ionic hydrogenation of, 728
monohydroxylation of, 663, 664
  competitive, 675
nitration of, 636
  competitive, 638
phenylamination of, competitive, 660
propylation of, 554, 557, 558
sulfonation of, 633
  transethylation of, 557, 587
  transnitration of, 643
Benzenes
  alkenylation of, 594
  alkylation of, 556
cyclialkylation of, 595
  hydroxyalkylation of, 582
  benzene dication, bisallylic, 147
  benzenesulfonic acid, protonation of, 635
  benzenium-iminium dications, 416
  benzenium ion(s), 126
  1H NMR spectrum of, 126
Benzhydryl
cations, 140, 141
  as indicators, 15–17, 19, 58
  chlorides, alkylation with, 752
Benzochloronium ion, intermediate, 380
Benzocyclobutadiene dications, 161
Benzocyclopropenium ions, 158
1,5-Benzodiazepines, synthesis of, 695
Benzo[e]dihydropyrenes, protonation of, 131
Benzo-3-dioxolium ion, 174
Benzoic anhydride, as acylating agent, 610
Benzonitrile(s)
  electrochemical oxidation of, 753, 754
  in Ritter reaction, 743
Benzonorbornenyl cations, 134
Benzopentaphene, synthesis of, by cyclodehydration, 607
Benzopyrenium cations, 130
para-Benzoquinone, Diels–Alder reaction of, 735, 736
Benzotrifluoride, nitration of, 639
4H-1,2-Benzoxazines, synthesis of, 690, 691
Benzoyl chloride, as acylating agent, 609, 611
Benzyl alcohol(s)
  alkylation with, 560, 565, 566, 750, 751
  in Ritter reaction, 743
Benzylamines, propargyl-substituted, ring closure of, 602
1-Benzylamino-1-methylthio-2-nitroethane, ring closing of, 693
Benzylation, competitive, 560
Benzylation of aromatics, 576
Benzyl azide, in aza-Mannich reaction, 751
Benzyl cation(s)
calculated structure of, 143
complexed to Cr(CO)_3, resonance forms, 205
in intramolecular acylation, 613
rotational barrier of, 142
substituted, 142
Benzylic alcohols
alkylation with, 561
chiral, 146
oxidation of, 645
Benzylic cation, 561, 752
Benzylic chloride, alkylation with
565, 576
BF_3, 44, 434
alkylation of aromatics with, 573
in generating acetyl tetrafluoroborate, 189
in preparation of NO_2^+ salt, 636
BF_3–2CF_3CH_2OH, 45, 638, 698, 725, 733
BF_3–H_2O, 45
in Fries rearrangement, 618
in halogenation of aromatics, 657
in ionic hydrogenation, 728
in nitration, 638
thioacetalization in, 676
BF_3·OMe_2, 339, 354
BF_3·OEt_2, 462
BH_6^+ ion, 213
B_6H_10, 272
Bicyclic enones, carboxylation of, 625
Bicyclobutonium ion(s), 241, 242, 244, 245, 246, 743
Bicyclobutonium-type structures, additivity of chemical shifts, 244, 245
Bicyclo[4.2.2]decane-type structure, in polyheteroatom cations, 443, 446
Bicyclo[4.0.0]enones, ionic transfer hydrogenation of, 731
Bicyclo[3.2.0]heptadienyl cation, 260
Bicyclo[2.2.1]heptane, see Norbornane
Bicyclo[2.2.1]heptane-2-yl nitride intermediate, 642
Bicyclo[2.2.1]heptyl cation, see 1-Norbornyl cation
Bicyclo[3.2.0]hept-3-yl cation, 224
Bicyclohexane, protonated, 113
cis-Bicyclo[3.1.0]hexan-3-ol, 265
Bicyclo[3.1.0]hexane-type arrangement, in polyheteroatom cations, 446
2-Bicyclo[2.1.1]hexyl cation, 240
σ-bridging in, 240, 241
calculated structures of, 241
labeling studies of, 241
Bicyclo[3.2.2]nonatrien-2-ol, ionization of, 253
Bicyclo[3.2.2]nona-3,6,8-trien-2-yl cations, 253
Bicyclo[4.3.0]nonatrienyl cation, 254
Bicyclo[2.2.2]octane, reaction with NO_2^+ salts, 642
Bicyclo[2.2.2]octane-1,4-diyl dication, 148, 264, 265
Bicyclo[2.2.2]octane structure, in polyheteroatom cations, 446
Bicyclo[3.3.0]oct-1-yl cation, 113, 114
Bicyclo[2.2.2]octyl-1-oxonium hexafluorosilicate, 323
Bicyclopentyl cation, 241
Bicyclo[3.3.3]undeca-1,5-yl dication, 148, 149
Bicyclo[3.3.3]undecyl cation, 118
Biginelli reaction, 694
Binaphthylic dication, 182
Binding energy differences, 236
Biphenyl
acylation of, 611
alkylation of, 568
in polycondensation, 746
Biphenyl-4-carboxaldehyde, alkylation with, 578
Biphenylenes, two-electron oxidation of, 161
Bisadamantyl cation, 228
Bisadamantylmethyl cations, 109, 110
Bisalkenyliodonium salts, 369
Bis[bis(4-methylphenyl)tellurium] oxide, X-ray studies, 360
N,N-Bis(carboxy)-1,2-diaminoethane, diprotonated, 198
Bis(chloromethyl)chloronium ion, 365
cis-1,2-Bis(chloromethyl)cyclohexane, ionization of, 379
2,6-Bis(chloromethyl)mesitylene, ionization of, 147
[Bis(cyclopropylidene)methane], protonation of, 136
Bisdiazonium dication, 389
Bis(diisopropylamino)borenium ion, 398
Bis(dimethylamino)phosphenium ion, 418
$^{31}$P NMR chemical shift, 418
Bis(dimethyleneammonium) salts, substituted, X-ray studies, 381
1,8-Bis(diphenylmethyl)cation/naphthalenediyldication, X-ray studies, 379, 380
gem-(Bisfluoroamino) derivative, nitrolysis of, 642, 643
Bisformamidinium cation, X-ray studies, 203
Bisguanidinium dications, X-ray studies, 203
$\text{3,3-Bis(halomethyl)trimethylenebromonium ions, 375}$
Bishomoaromatic dication, sandwiched, 261
$\sigma$-Bishomoaromatic species, 263, 264
$\sigma$-Bishomoconjugation, 263
1,4-Bishomotropylium ion, 254
folded structure of, 262
Bis-hydroxylation, 673, 674
Bisiminium salts, 612, 613
Bismethano[14]annulene, protonation of, 132
1,2-Bis(methoxyphenyl)ethanes, aromatic cyclization of, 719
1,3-Bis(methoxyphenyl)propanes, aromatic cyclization of, 718, 719
Bis(4-methylphenyl)telluride, two-electron oxidation of, 360
Bisphosphenium dications, 422
Bis(pyridine)iodonium(I) tetrafluoroborate, monoiodination with, 658
Bissulphonium salts, aurated, X-ray studies, 350
2,2'-Bis(triaryl)methyl)cations, 151
1,3-Bis(trichloromethyl)benzene, trifluorination of, 651
1,1-Bis(trifluoromethyl)-2-arylethanols, synthesis of, 562, 563
3,5-Bis(trifluoromethyl)benzoyl chloride, acylation with, 610
Bis(trifluoromethyl)methane diazonium ion, 384
Bis(trimethylsilyl) peroxide, as oxygenating agent, 675, 676
$[\text{BMIM}][\text{PF}_6]$ in alkylation of aromatics, 560, 561 in terpenoid cyclization, 712
Boremium ions, 397
complexed to 2,2'-bipyridine, X-ray studies, 400 $[\text{Cp}^*\text{Fe(CO)}_2]$, 399, 400 with donor ligands, 399 endo-Borneol, acylation of, 677
Boron tris(triflate), $\text{B(OTf)}_3$, 46, 422 in acylation of aromatics, 609 in alkylation of aromatics, 567, 571 meta selectivity, 567, 570 inducing isomerization, 567 in isomerization, 535–537
Boron tris(trifluoromethanesulphonate), see Boron tris(triflate)
$\text{B(OTf)}_3$, see Boron tris(triflate)
$\text{Br}_3^+\text{AsF}_6^-\text{salt, X-ray studies, 431}$

$\text{BrF}_2^+\text{ion, 434}$
$\text{BrF}_2^+\text{SbF}_6^-\text{salt, X-ray studies, 434, 435}$
$\text{BrF}_4^+\text{Sb}_2\text{F}_{11}^-\text{salt, X-ray studies, 436}$
$\text{Br}_2$–HF–SbF$_5$, bromination with, 655, 656
Bridgehead cations, 116, 573
Bridgehead halide–Lewis acid complexes, in alkylation, 573
$\text{Br}^+\text{ion, in bromination, 655, 656}$
$\text{Br}_2^+\text{ion, 431}$ disproportionation of, 431 involvement in bromination, 656 $\text{Br}_3^+\text{ion, 430, 431, 439}$ disproportionation of, 431 $\text{Br}_5^+\text{ion, 428, 432}$
Bromine cations, 430
Bromine trifluoride, self-ionization of, 434
1-Bromoadamantane, adamantylation with, 574, 576
Bromobenzene
adamantylation of, $\text{para}$ selectivity in, 576, 577
alkylation and acylation of, 617, 618
$\beta$-Bromocarbenium ion, 373
Bromocarbonyl cation, BrCO$^+$, 623
1-Bromocyclopentadiene, precursor in matrix isolation, 267
Bromofluorination, 655
7-Bromoniabicyclo[4.1.0]heptane, 378, 379
Bromonium ion
  bridged intermediate, 361
clear concept, 361
Bromophenols, isomerization of, 656
meta-Bromophenols, preparation of, 655, 656
1-Bromopropargylic amines, trifluorination of, 651, 652
1-Bromopropargylic imides, trifluorination of, 651, 652
N-Bromosuccinimide
  in azidobromination, 742
  in bromofluorination, 655
  in fluorination, 652
1-Bromo-3,5,7-trimethyladamantane, adamantylation with, 574
Brønsted acids, in acylation of aromatics, 609
Brønsted superacids, 35
  generated, in photodecomposition, 748, 749
Br2+Sb3F16/C0 salt, X-ray studies, 432
Br5+SbF6/C0 salt, X-ray studies, 432
1,2-Br shift, 656
Bullvalene, 253
[(tert-Bu)2MeSi]2[(tert-Bu)2Si]Si+ ion, methyl exchange in, 408
[(tert-Bu)2MeSi]3Ge+ ion, 411, 412
[(tert-Bu)2MeSi]3Si+ ion, 408
[(tert-Bu)2MeSi]3Sn+ ion, X-ray studies, 414
[(tert-Bu)3PN]2B+(C6F5)4B/C0 salt, X-ray studies, 398
Bu3Sn+CB11Me12− salt, X-ray studies, 414
Bu3Sn+H(C6F5)3B− salt, 413
Bu3Sn+TFPB− salt, 413
n-Butane
  alkylation of, by butyl cations, 545
  ethyl cation, 546
  bromination of, 651
  carbonylation of, 624, 625
  ethylation of, 546, 549
  formation of, in ethylation of ethane, 221, 547
  H–D exchange of, 515
  ionization of, 504
  isomerization of, 68, 503, 524, 529, 533, 534
  protonation of, 221–223
1,4-Butanediol, intermediate, 596
2,3-Butanediol, diprotonated, rearrangement of, 316
Butanes
  alkylation of, by butyl cations, 546
  isopropyl cation, 546
  isomerization equilibria of, 526
Butenes, alkylation of adamantane with, 548
Butonium cations, calculated structures of, 220, 221, 222
n-Butyl alcohol, protonated, cleavage of, 315
tert-Butyl alcohol
  as alkylating agent, 560
  protonated, on Ru(001) surface, 315
tert-Butylbenzene, adamantylation of, para selectivity, 576
sec-Butylbenzene, byproduct in alkylation, 558
para-tert-Butylcalix[4]arene, de-tert-butylation of, 588
tert-Butyl carbamate, protolytic ionization of, 198
n-Butyl cation, rearrangement of, 315
sec-Butyl cation
  alkylation by, 545, 546
  1,2-hydride shift in, 225
  hydrogen-bridged, 226
  isotope scrambling in, 102–104
  line-shape analysis of, 225
tert-Butyl cation, 93, 179, 220, 226, 315, 320, 321, 334, 516, 542
  alkylation by, 545, 546, 548
  13C NMR shifts of, 96
  13C scrambling in, 102, 103
deuterated, in H–D exchange, 219
  ESCA spectrum of, 107, 235
  generation of, in superacids, 94, 510
  1H NMR spectrum of, 95
  in isobutane–isobutylene alkylation, 544
  in Magic Acid, 104, 504
  nutation NMR spectroscopy of, 107
  in oxygenation of alkanes, 661, 670
  in protolytic condensation of methane, 552
  IR frequencies of, 105, 106
  IR photodissociation spectrum of, 104
  X-ray studies, 107
Butyl cations, alkylation with, 546, 547
tert-Butyldimethylaminophosphonium ion, 418
$^{31}$P NMR chemical shift of, 418
1-(tert-Butyldimethylsilyl)bicyclobutonium ion, 244
3-endo-(tert-Butyldimethylsilyl)
bicyclobutonium ion, 244
tert-Butyl fluoride, alkylation with, 567, 570
1-tert-Butyl-1-fluoroethyl cation, intermediate, 373
tert-Butyl hydroperoxide, 661
n-Butyl methyl ether, protonated, cleavage of, 320
sec-Butyl methyl ether, protonated, cleavage of, 321
tert-Butyl methyl sulfide, protonated, cleavage of, 334
tert-Butyloxenium ion, intermediacy of, 425
tert-Butylphenols, de-tert-butylation of, 587
(tert-Butyl)$_3$SiOH$_2^+$Br$_6$CB$_6^-$H$_6^-$, X-ray studies, 318
n-Butyl thiol, protonation and cleavage of, 333
sec-Butyl thiol, protonation and cleavage of, 333
tert-Butyl thiol, protonation of, 332
Butyramides, N-substituted, Knorr cyclization of, 687, 688
C$_{60}$, protonation of, 165
CAD, see Collisionally activated dissociation
Cage dications, 262–265
Calorimetry, 92, 237
Camphene, protonation of, 707
Camphene hydration, 707
Camphene hydrochloride, rearrangement of, 83
Camphor, rearrangement of, 706, 707
Carbamic acid, protonated, 198
Carbenium ions, 85
in alkane isomerization, 516
in cationic polycondensations, 744
in cationic polymerizations, 744
controversy of, 503
disproportionation of, 524, 620
in exchange, 518
$\alpha$-ferrocenyl, 205, 206
formation of, 503, 525, 527
generated by anodic oxidation, 529, 553
hexafluoroantimonate salts, alkylation by, 544
as initiators, in alkane isomerization, 529
isomerization of, 525, 527
reactions of, 523
reduction of, 528
reversible disproportionation of, 524
$\beta$-scission of, 540–542
tertiary, in carboxylation, 620
Carbenium–oxonium dications, 598, 599
Carbocation(s), 85, 86, 688, 740
adamantyl, 257
with aromatic stabilization, 157
azulenyl-substituted, 160, 161
9-barbaralyl, 253
classification of, 86
degenerate 1,2-sifts in, 225
equilibrating (degenerate), 206
halogen-substituted, 167
general definition of, 85
generation of, 87, 88
by using NO$^+$, 644
heteroatom-stabilized, 167
stability of, 195
higher-coordinate, 86, 206
homoaromatic, 258
hydroxylated, 172
long-lived, observation of, 84
methods to study, 88
nonclassical, 206
pentacoordinate, in alkylation, 548
perfluorophenyl-substituted, 168
pyramidal, 267
carcinogenic, 511
rearrangement of, 101, 116, 118, 224, 225, 253–255, 260, 315, 511, 523, 531, 699
$\beta$-silyl-substituted, 111
$sp^3$ hybridized, 150, 573
in superacid systems, 83
trifluoromethyl-substituted, 168
trivalent, 93
Carbocationic intermediate(s), 503, 527, 535, 561, 562, 576, 579, 716
in carbon scrambling, 545
in cracking, 539, 540
in exchange, 506, 508, 510
in hydride transfer, 546
in hydrocarbon transformations, 550
Carbocationic intermediate(s) (Continued)
- in isomerization, 535, 537, 540, 750
- in polymerization, 744
- protonated cyclopropane, 101–103, 113, 525, 527, 531
- pyramidal, 224
- in rearrangement, 511, 714, 716

Carbodications, 147
- bicyclic, sulfur-stabilized, 194, 195
- pentacoordinate, in formylation, 632

Carbon dioxide
- activated complex of, 627
- carboxylation of aromatics with, 627
- protonation of, 180

Carbon disulfide, alkylation of, 632, 633

Carbonic acid, protonated, 179, 180
- calculated structures of, 180, 181
- X-ray studies, 180

Carbonium ion(s), 85, 86
- in alkylations, 544–548, 550, 552
- in carboxylation, 631, 632
- in cationic oligocondensations, 744
- in H–D exchange, 220, 510, 511
- intermediates, in isomerization, 535
- in NO$_2^+$ insertion, 636, 637, 642
- in oxyfunctionalization of alkanes, 661, 662, 669–671
- in protonation of hydrocarbons, 207, 212, 216, 218, 219, 505, 623

Carbon monoxide
- in acylation, 616, 617
- formylation with, 627–632
- in Koch–Haaf reaction, 618–622
- protonated, 632
- protonation of, 188
- solubility of
  - in ionic liquid, 631
  - in triflic acid, 619
- suppressing exchange by, 518
- trapping of carbenium ions with, 506, 510, 621, 625

Carbon scrambling, 102, 103, 112, 255, 504, 545

Carbon shift, 654

Carbon tunneling, 233

Carbonylation, 453
- of propane, 621–624
- oxidative, 626, 627
- reductive, 453, 454, 457
- solvolytic, 454

Carbonyl compounds
- acetalization of, 677
- aromatic
  - as indicators in acidity measurements, 18, 19, 322
  - hydroxylation of, 665
  - diprotonation of, calculations, 173
  - hydroxy-substituted, ionic hydrogenation of, 733
- methylenation of, 755
- oxygenation of, 671, 672
- polycondensation of, 746
- thioacetalization of, 676

Carbonyl group, reduction to methylene group, 733

Carbonyl sulfide, alkylation of, 632, 633

Carborane superacids, 41, 42, 127

Carbosulphonium ions, 193, 194

Carbotrications, 131

Carboxamides
- formation of, in Ritter reaction, 685, 742
- oxygenation of, 674

Carboxonium–ammonium dications, in alkylation, 580

Carboxonium ions, 172, 425
- acidic, 172
- alkylated, 185
- cyclic, 185, 652, 670, 671
- in glycosylation, 703, 704
- in oxygenation, 668–671
- O-silylated, 188
- stability of, 182
- X-ray studies of, 173

Carboxonium ion salts, 84
- cyclic, 185

Carboxylation, 618

Carboxylic acid alkyl esters, alkylation with, 585

Carboxylic acid anhydrides, protonated, cleavage of, 179

Carboxylic acids
- addition to alkenes, 738
- protonated, 174, 734
- trialkysilylation of, 677, 679
- unimolecular cleavage of, 175
- unsaturated, esterification of, 734

Car–Parrinello simulation, 209, 313
Caryophyllene derivatives, rearrangements of, 716
diepoxides, ring contraction of, 714
Cationic complexes, bimetallic, 204
Cationic intermediates, 646, 647
protonation of, 501
Cationic polymerization, photoinitiated, 748, 749
Cations, reactivity of
in polymerization, 744
towards benzene, 556
CBr₄⁻AlBr₃
in acylation, 616, 617
in alkylation, 591
CBr₄⁻2AlBr₃
bromination with, 651
in carboxylation, 625
in formylation, 631
CBr₅(OTeF₅)⁺/C₀⁺ cations, 171
C–C bond
cleavage of, 510, 539
electrophilic reactivity of, 505

oxygenation of, 676
Diamantyl cation(s), rearrangement of, 118, 119
2,2'-Diaminobiphenyls, ring closure of, 689
Diamondoidyl cations, calculated structure of, 119
Diarylacetylenes, fluorination of, 646
Diaryl(alkoxy)sulfonylum perchlorates, 344
Diaryl ethers, protonation of, 322
Diarylhalonium ions, 361, 369, 370
Diaryl-Ν₃-iodanes, 370
Diarylidonium salts, 370
in photoinitiated cationic polymerization, 748, 749
3-(Diaryl)methylene)isobenzofuranones, formation of, 583, 584
2,5-Diaryl-2,5-norbornadiyl dications, 153
1,3-Diarylpropynones, cyclization of, 600, 601
1,3-Diaza-2-azoniaallene cations, substituted, 388
1,3,2-Diazaborinocenium ring cations, X-ray studies, 399
1,3,2-Diazaphospholes, X-ray studies, 418
α-Diazoacetamides, ring closing of, 608
2-Diazo-5α-cholestan-3-one, protonated, 384
Diazomethane
diprotonated, 385
protonation of, 202, 384
Diazonium ion(s), 383
2,6-disubstituted, Nα–Nβ inversion, 386
Dibenz[a,h]anthracene, ionic hydrogenation of, 733
Dibenzocyclobutadiene dications, 161
Dibenzo[b,f]pentalene dications, 164
Dibenzo[b,f]pentalenes, two-electron oxidation of, 164
Dibenzyl ether, byproduct, in alkylation, 560
trans-1,2-Dibromocyclopentane, ionization of, 377
Di-tert-butoxyl tert-butanolate, protonation of, calculations, 174
Di-tert-butylcarbodiimide, methylation of, 382
Di-tert-butyl carbonate, protonated, cleavage of, 179
2,6-Di-tert-butyl-para-cresol, in trans-tert-butylation, 588
(2,4-Di-tert-butyl-6-methyl)benzyl cation, rotational barrier of, 142
Di-tert-butyl sulfide
protonated, cleavage of, 334
synthesis of, 335
1,3-Dicarbonyl compounds, C-alkylation of, 750, 751
Dicationic intermediates
in acylation of aromatics, 610
in alkylation of aromatics, 556, 557, 562, 563, 580, 592–595
in cyclialkylation, 603, 604, 606
in cyclization, 600, 601
in fluorination
Dicationic intermediates (Continued)
of alkaloids, 652, 653
of imines, 650
in lactone formation, 734
Dicationic species, protosolvated
in cyclialkylation, 597, 606
in isomerization, 725, 726
Dications
with aromatic stabilization, 157
with bicyclo[2.2.1]heptyl skeleton, 153
bis(3-guaiazulenyl)-substituted, 156
cage, 262–265
cyclopropyl-substituted, 153
1,5-distonic, 151
in halogena
genations, 658
with naphthalenediyl skeleton, 155, 158
X-ray studies, 155
polycyclic, arene, 162
in ring closing, 692, 693
with two cyclopropenium ion moieties, 158
1,1-Dichloro-1-alkenes, trifluorination of, 651
ortho-Dichlorobenzene, alkylation of, 581
para-Dichlorobenzene, in cyclialkylation, 606
trans-1,2-Dichlorocyclopentane, ionization of, 378
Dichloromethyleneiminum salts, 200
Dichloropentamethylbenzyl cation, 147
Dicyanoiodonium ion, 365
Dicyanometacyclophanediene, ring closure of, 726
Dicyclophe
ym bromonium ion, 365
Dicyclophe
carbonyl cation, 269
Diels–Alder reactions, 735–737
intramolecular, 737
Dienes, esterification with, 734
Dienones, protonated, reduced in ionic hydrogenation, 728
1,3-Dienyl-2-cations, calculations, 136, 137
π-Dienyl cations, complexed to metal, 204
Diepoxytetralin, ring opening of, 697, 698
meta-Diethylbenzene, selective formation of, 587
Diethylbenzene, transethylation of benzene with, 557, 557
Diethylbenzenes
disproportionation of, 587
isomerization and transalkylation of, 589
Diethylhalonium hexafluoroantimonates, alkylation with, 589–591
Diethylhalonium ions, ethylation with, 591
Diethyl oxalate, as alkylation agent, 585, 586
Diethyltellurium ion, 351
Diffuse reflectance IR, for acidity measurement, 28
4,4'-Difluorobenzhydryl cation, 141
1,3-Dihaloalkanes, ionization of, 374
Dihalobutanes, ionization of, 375, 376
1,4-Dihalocubanes, methylation of, 365
α,α-Dihalomethyl methyl ethers, ionization of, 184
Dihalonium ions, 377
1,5-Dihalopentanes, methylation of, 377
Di-μ-hydrido bridging, 248
cis-8,9-Dihydro-1-indenyl structure, 262
2,3-Dihydro-1H-indoles, bromination of, 656
3,6-Dihydro-2H-pyran, synthesis of, 683
Dihydropyridones, aryl-tethered, cyclization of, 606
2,16-Dihydrovincentiformal, hydroxylation of, 666
2,2'-Dihydroxybiphenyls
ring closure of, 681, 682
trans-tert-butylation of, 588
Dihydroxy compounds, cyclodehydration of, 681
Dihydroxynaphthalenes, ionic hydrogenation of, 729
4,4'-Diisobutyl-2,6-dimethylheptyl cation
di-μ-hydrido bridged, 248
hydrogen exchange in, 249
Dimerization, in alkenylation, 594
para-Dimethoxybenzene, in cyclialkylation, 606
3,4-Dimethoxybenzyl alcohol, cyclialkylation of, 565
Dimethoxyfluorosulfonium ion, 343
2,5-Dimethoxycyclohexadecanone, in cyclialkylation, 596
Dimethylacetals, 678
Dimethylamino groups, complexing, 425, 426
N,N-Dimethylaniline, nitrozation of, 644
Dimethylbiphenyls, isomerization of, 750
2,3-Dimethylbutadiene, Diels–Alder reaction of, 736
2,2-Dimethylbutane, in hexane isomerization, 527, 528, 530
2,3-Dimethylbutane in hexane isomerization, 527, 528 isomerization of, over solid superacids, 531 oxygenation of, 668
Dimethyl carbonate, protonated, X-ray studies, 180
Dimethyl cubane-1,4-dicarboxylate, protonated, 177
1,5-Dimethylcyclodecyl cation, 1,5-μ-hydrido bridging, 250
1,3-Dimethylcyclohexyl cation, degenerate shift in, 247
1,4-Dimethyl-1-cyclohexyl cation, 1,4-hydrogen shift in, 247
Dimethylene cyclopropylmethyl cation, 120, 122
1H NMR spectrum of, 122
Dimethyl decalins, formation of, 553
O,S-Dimethyl dithiocarbonate, protonated, X-ray studies, 193
1,16-Dimethylcubane, synthesis of, 537, 538
Dimethyl ether, protonated
alkylation with, 565
as byproduct, in alkylation, 564 calculated structure of, 319 carboxylation of, 619
1H NMR spectrum of, 320
as methylating agent, 565
Dimethyl ether–5 HF, 41 hydrofluorination with, 655
Dimethyl ether–HF complex, in transformations of peptides, 676
Dimethylethylene halonium ions, 373
Dimethyl fumarate, Diels–Alder reaction of, 735
Dimethylhalonium dications, protonated, calculated structure of, 367
Dimethylhalonium hexafluoroantimonates, as alkylating agents, 589–591
Dimethylhalonium ions, 363 as methylating agents, 591
2,6-Dimethyl-1-heptanol, carboxylation of, 620
2,6-Dimethylheptyl cation(s), 248, 249
2,5-Dimethyl-2-hexyl cation, 1,4-hydrogen shift in, 247
3,4-Dimethyl-4-homoadamantanol, ionization and rearrangement of, 699
Dimethyloctahedralanes, ionization of, 669
Dimethylhydrazones, oxidative cleavage of, 641
Dimethyl maleate, Diels–Alder reaction of, 735
2,6-Dimethylmesitylene-2,6-diyl dication, 147
Dimethylmethylcarboxonium ion, in oxygenation, 661, 668, 669
Dimethylidanimethanes, 129, 130
2,2-Dimethylocycloalkanes, protonated, calculations, 321, 322
Dimethyl oxalate, as alkylating agent, 585
2,2,-Dimethyl-6-oxoquinuclidine, N-protonation of, 196
2,4-Dimethylpent-2-yl cation, degenerate shift of, 247
Dimethyl peroxide, protonated, 330
Dimethylselenonium ion, 351
Dimethyl sulfide, protonation of, 335
Dimethyl sulfoxide, mono- and diprotonated, 343
Dimethyltellurinium ion, 351
2,5-Dimethyltetrahydrofurans, protonated, 316
3,10-Dimethyltricyclo[5.2.1.02,6]deca-4,8-dien-3,10-diyl dications, 153, 154
Dimethyl(trimethylsilyl)sulfonium ion, 348
Dimethyl trithiocarbonate, protonated, X-ray studies, 193
Diols cyclialkylation with, 595
dicarboxylation of, 620, 621 enhanced proton affinities of, 317 ionization of, 151, 152
1,2-Diols dehydration of, 698
pinacolone rearrangement of, 698
Dioxacycloalkanes, ring-opening polymerization of, 746
3-Dioxolium ions, 174
Dioxygenyl hexafluoroantimonate, 439
4,4′-Diphenoxycetophenone, in polycondensation, 746
Diphenyl carbonate, deacylation of, in hydroxylation, 665
Diphenyl ether, in polycondensation, 746
3,3-Diphenylindanone, product of dehydrative decarbonylation, 583
Diphenylmethane, formation of, 578, 584, 585
Diphenylmethyl cation(s), 140, 141, 579
1,3-Diphenylpropanones, cyclodehydration of, 596
cis-6,8-Diphenyl-5,6,7,8-tetrahydroisoquinoline, formation of, 592
cis-5,7-Diphenyl-5,6,7,8-tetrahydroquinoline, formation of, 592
4,4-Diphenyltetrahydroquinoline, product of dehydrative decarbonylation, 583
Diprotiomethonium trication, see CH$_3^{3+}$ trication
Diprotonated intermediates in acylation, 612, 615, 616 in addition, 741 in alkylation, 592, 593 in cyclodehydration, 597–601 in ionic hydrogenation, 730 in polycondensation, 746 in ring closure, 726 Diselenonium dication, cyclic, 359 with hypervalent Se and Te, X-ray studies, 360 Disilyl cations, hydrogen-bridged, X-ray studies, 406 Disproportionation in adamantylation, 571 in alkane isomerization, 529, 530 of alkylbenzenes, 586, 587 of carbenium ions, 524, 620 of dialkylhalonium ions, unsymmetrical, 366 of halogen cations, 429–431, 433, 435, 436 reversible, 524 of Se$_{10}^{2+}$ ion, 443 suppressing of with cycloalkanes, 530 with hydrogen, 529 Disulfonium dications, 358, 359 calculations, 358 with hypervalent Se and Te, X-ray studies, 359 X-ray studies, 358, 359 1,5-Dithiacyclooctane, ionization of, 358 1,2-Dithiin, substituted, two-electron oxidation of, 348 Dithiocarboxylation, 632 Dithioesters, protonation of, 192 Dithiolenes, desulfurative fluorination of, 647 Ditriaxane-2,2-dimethyl alcohol, 246 Ditriaxane-2,2-dimethyl dication, 245 nonclassical structure of, 246 DMEPHF, see Dimethyl ether–5 HF 1,16-Dodecahedradienes, ionization of, 263 Dodecahedran-1,16-diyl dication, 149, 150 Dodecahedryl cation, 119, 120 1-Dodecene, alkylation of aromatics with, 559 $\sigma$-Donor ability of C–C and C–H bonds, 545 of single bonds, 505 $\pi$-Donors, 85 $\pi$-Donors, 85 $\sigma$-Donors, 85 Dowex-50, 554 Drimenol, cyclization of, 712 $\text{D}_2\text{SO}_4$ deuteriation of isobutane in, 219, 516, 517 H–D exchange of methane in, 509 $\text{D}_3\text{SO}_4^{+}\text{SbF}_6^{-}$ salt, X-ray studies, 343 Durene, alkylation of, 562 Dynamic NMR, for acidity measurements, 18 $\beta$-Effect, see $\beta$-Silyl effect Electrochemical measurements, 24 Electrochemical oxidation of alkanes, in strong acids, 520 of aromatics, 752–754 Electrocyclization mechanism, 598, 691 Electronic spectroscopy, 92, 104, 441 Electrophilicity, role in alkylation of aromatics, 556 Electropolymerization, 749, 750 Enium ions of group 13 elements, 397 of group 14 elements, 401 of group 15 elements, 415, 423 of group 16 elements, 424, 425 Enoldiazonium ions, 386 Enol ethers, ring closure of, 682
Enones, protonated, reduced in ionic hydrogenation, 728
Enzymes, as superacid catalysts, 7
Epiquinidine acetate dihydrochloride, difluorination of, 653
9-Epiquinine
difluorination of, 653
oxygenation of, 666
9-Epiquinine acetate
difluorination of, 653
oxygenation of, 666
Episelenonium ion, X-ray studies, 353
Episulfonium ions, 337, 339
Epoxides
optically active, to form oxazolines, 692, 693
protonated, 666
Epoxy alcohols, chiral, ring opening of, 697
2,3-Epoxygeraniol, cyclization of, 713, 714
2,3-Epoxy-cis-pinane, ring contraction of, 714
Epoxy resins, emulsified, cationic polymerization of, 748, 749
EPR spectroscopy, 164
for acidity measurement, 28
Ergoline, synthesis of, 604, 605
ESCA spectroscopy, 92, 207, 228, 235
ESR spectroscopy, 267, 439
Esterifications, 734
Esters
alkylation with, 336
carboxylation of, 619
cleavage of, 734, 735
protonated, unimolecular cleavage of, 175
Estrane, unsaturated, ionic hydrogenation of, 728
Estrone
hydroxylation of, 666
ionic hydrogenation of, 728
Estrone acetate, hydroxylation of, 666
Estrone derivatives, phenol–dienone rearrangement of, 722
Et<sub>2</sub>Al<sup>+</sup>CB<sub>11</sub>H<sub>12</sub>X<sub>6</sub><sup>−</sup> salts, X-ray studies, 400, 401
Et<sub>2</sub>CIS<sup>+</sup>SbCl<sub>6</sub><sup>−</sup> salt, 341
Ethane
alkylation of, by ethyl cation, 546
bromination of, 651
ethylation of, 220, 221, 547–549
hydroxylation of, 663
oligocondensation of, 553
oxygenation of, 670, 673
protonated, in reactions on zeolites, 217
protonation of, 216
Ethane-1,2-diol, 678
Ethanol, see also Ethyl alcohol
protonated, on Ru(001) surface, 315
protonation of, 313
proton-bound dimer of, 314, 315
Ethano phenantremium–carboxonium trication, 164
Ethene, alkylation of adamantane with, 548
Ether formation, 700
Ethers, protonated, 319
bidentate complexes of, 319
cleavage of, 319
Ethide shift, 531
Ethonium ion, 216
tetraaurated, 218
Ethyl acrylate, Michael addition of, 738
Ethyl alcohol, see also Ethanol
protonated, reactivity of, 315
Ethylarylationonium ions, 368
Ethylation of
benzene, 554, 557
ethane, 221, 547, 548
methane, 547, 548
propane, 548
Ethylbenzene
alkylation of, 558, 574, 589, 590
formation of, in transalkylation, 589
Ethylcarboxonium ion, 622–624
Ethyl cation, 623
direct alkylation with, 546, 548
Ethylcyclohexane, carboxylation of, 625
Ethyl N,N-diisopropyl carbamate,
protonation of, 196
Ethyl dimethylxoxonium ion, cleavage of, 328
Ethyl dithiobenzoates, preparation of, 633
S-Ethyl dithiocarboxonium fluoroantimonates, preparation of, 632, 633
Ethylene
alkylation with
of alkanes, 546–549
of aromatics, 554, 557, 558
polymerization of, 750
Ethyleneanthracenium ions, 134
Ethyleneareniun ions, 132
Ethylenebenzenium ion, 133
charge delocalization in, 133
Ethylene 1,2-dications, 155, 156
Ethylene glycol, diprotonated, rearrangement of, 316
Ethylenehalonium ions, 372
Ethylenenaphthalenium ions, 133
Ethylenephenonium ions, 132
Ethyl fluoride–antimony pentafluoride complex, see Ethyl fluoroantimonate
Ethyl fluoroantimonate, alkylation with, 363, 366, 367, 544, 632, 633
3-Ethyl-5-methyl-1-adamantyl cation, 699
Ethyl N-methyl carbamate, protonated, hindered rotation of, 199
Ethyl methyl ketone, protonated, 316
1-Ethyl-2-nitrobenzene, ring closing of, 690
Ethyl pentadienoates, ring closing of, 685, 686
Ethyl pivalate, 510, 513
Ethyl shift, 531, 532, 681
Ethyl thiobenzoates, preparation of, 633
S-Ethyl thiocarboxonium fluoroantimonates, preparation of, 632, 633
Ethyl trifluoropyruvate, alkylation with, 582
Ethynyl ketene-S,S-acetal, aza-Diels–Alder reaction of, 687
5-Ethynyl-1-methyl-imidazole, as alkylating agent, 594
Ethynlypyridines, as alkylating agents, 594, 595
Et3O+SbCl6−, alkylation with, 385
Et3Si+ (C6F5)3A− salt, see also para-Triethylsilyltoluenium ion
X-ray studies, 402
[Et3Si(C6H4Me)]+ cation, 127, 128
Et3SiH–BF3–2CF3CH2OH, ionic hydrogenation with, 733
Exchange rate, for acidity measurements, 18 suppressed by CO, 518

trans,trans-Farnesol, cyclization of, 712
E,E-Farnesol and acetate, cyclization of, 712
Farnesols, selective cyclization of, 711, 712
E,E-Farnesyl phenylsulfone, cyclization of, 712
[(F3As)Au]+SbF6− salt, X-ray studies, 459
[(F3As)AuXe]+Sb2F11− salt, X-ray studies, 459
Fatty acids, esterification of, 734
Fatty esters, epoxidized, ring opening of, 696
[Fe(CO)6]+BF4− salt, X-ray studies, 456
[Fe(CO)6]2+ (Sb2F11−)2 salt, X-ray studies, 455
Fe2++H2O2, as oxidant, 673
Ferrocene acylation of, 610
alkylation of, 584
α-Ferrocenyl carbenium ions, X-ray studies, 205, 206
Ferrocenyl group, stabilizing effect of, 206
β-Ferrocenyl-α,β-unsaturated derivatives, formation of, 584
Five-center four-electron bonding, 252, 266
Flemion, perfluorinated polymer resin acid, 67
Flowing afterglow, 22
9-Fluorenyle cation, 156, 157
Fluorenyl cations, intramolecular interconversion of, 269
9-Fluorenyle dications, 157
Fluorinated heterocycles, synthesis of, 695
Fluorination, 646, 647, 648
desulfurative, 646, 647
Fluorine, stabilizing effect of, 167
Fluoroantimonic acid, see HF–SbF5
Fluoroarylenonium fluoroborates, 461 para-Fluorobenzaldehyde, alkylation with, 578
Fluorobenzene adamantylation of, para selectivity in, 576
alkylation of, 582
arylation of, 610
gas-phase protonation of, 363
Fluoroboric acid, see HF–BF3
β-Fluorocarbenium ion, equilibrating, 373
Fluorocubane, alkylation of aromatics with, 573
Fluorocyclopentyl cation, calculated structure of, 169
Fluorocyclopentenium cations, 169
Fluorodiazonium salts, X-ray studies, 384
Fluorodihydroxysulfonium cation, 342, 343
X-ray studies, 342
Fluoromethanol, protonated, 184
Fluoromethylation, 336
S-Fluoromethyldiarylthiophenium salts, fluoromethylation with, 336
Fluoromethyl ketones, 695
exo-2-Fluoronorbornane, ionization of, 229
2-Fluoro-2-propyl cation, 167, 168
19F NMR spectrum of, 168
1H NMR spectrum of, 168
X-ray studies, 167
Fluorosulfuric acid, 36, 37, 38. See also HSO3F
Fluorosulfuric acid–antimony pentafluoride, see Magic Acid and HSO3F–SbF5
Fluoroxytrifluoromethane, fluorination with, 648
F2(MeO)S+ ion, 344
FNH3+HF2−/C0/C1 HF salt, 394
F2NH2+MF6/C0 salts, 394
in studying superacids, 25, 37, 39, 43, 50, 52–55, 58, 62, 73
F2NO+AsF6− salt, 450
F2NO+ salts, 450
FOH32+ salts, calculated structures of, 319
FOH22+ salts, calculated structures of, 319
FOH2+MF6−, 318
Formaldehyde
alkylation of benzene with, 585
carbonylation of, 626
diprotonated, calculated structure of, 193, 194
protonated, 172
protonation of, 317
Formalin
alkylation of benzene with, 585
in Prins reaction, 693
Formic acid, protonated, X-ray studies, 175
mono- and diprotonation of, calculations, 176
9-Formylanthracenes, deformylation of, 616, 617
Formylation
of aromatics, 627
reversibility of, 631
selectivities in, 627–630, 634
superelectrophilic, 631, 632
Formylation–rearrangement, superelectrophilic, 631, 632
Formyl cation, 628
calculated structure of, 188, 189
dual reactivity of, 629
insertion into tertiary C−H bond, 631
long-lived, 632
proton exchange of, 188
protosolvated, 628, 632
N-Formyl enamide, cyclization of, 724
Formyl fluoride, formylation with, 628
[μ-F(OsO2F3)2]+Sb2F11− salt, X-ray studies, 457
Four-center three-electron bonding, 432
Four-center two-electron bonding, 263, 264, 266, 430
[FO2XeFXeO2F]+ cation, 463
F4−/PHn+ salts, 394
FPS, in cyclization of pseudoionone, 721
FPSS, in cyclization of pseudoionone, 721
Fragmentation, 523
Friedel–Crafts
acid systems, 21
acylation, 71, 608, 614, 618, 630
reversibility of, 615
selectivity in, 630
alkylation, 366, 565–567, 573, 574, 577, 591
catalysts, 42, 595, 608, 633, 655
chemistry, 39
conjugate acids, 10, 61
dithiocarboxylation, 632
formylation, 628
nitration, 636
sulfonylation, 634
Friedel–Crafts-type reactions, 24, 46, 61, 72, 74, 206, 636
Fries rearrangement, 618
d- Fructofuranose, transformation into sugar oxazolines, 705
d- Fructopyranose, transformation into sugar oxazolines, 705
F2S+BF4− salt, X-ray studies, 340
F2SNMe2+As6− salt, X-ray studies, 345
[F2S≡NXeF]+AsF6− salt, X-ray studies, 464
[F3TeN(H)Xe]+AsF6− salt, X-ray studies, 464
FT–ICR mass spectrometry, 102, 209, 210, 217, 224, 238, 243, 331, 433
FT–IR, 124, 164, 455, 458
for acidity measurement, 28
 Fullerene cations, 164
 pentaarylated, 165, 166
 Fullerols, ionization of, 165

Hydroxybiindantetraone, alkylation with, 561
(R)-$\beta$-Hydroxybutyrolactone, ring-opening polymerization of, 746
Hydroxycarbonium ion, pentacoordinate, 661
Hydroxycarbonyl compounds, cyclization of, 598, 599
Hydroxycarboxylic acids, protonation of, 178
7-Hydroxychromanones, synthesis of, 682, 683
1-Hydroxycycloalkanecarboxylic acids, lactone formation of, 734
Hydroxydiazonium ion, theoretical studies of, 389
Hydroxyisoquinolines as alkylating agents, 591, 607
ionic hydrogenation of, 729–731
6-Hydroxytetralin, chlorination of, 656
HZSM-5 zeolite, 518

I$_3^+$AlCl$_4^-$ salt, X-ray studies, 428
I$_4^{2+}$(AsF$_6^-$)$_2$ salt, X-ray studies, 430
I$_5^+$AsF$_6^-$ salt, X-ray studies, 428
ICl$_2^+$ ion, 435
I$_2$Cl$^+$ ion, 435
disproportionation of, 436
ICl$_2^+$SbCl$_6^-$ salt, X-ray studies, 435
I$_4^{2+}$ dication, 430
IF$_2^+$AsF$_6^-$ salt, 434, 435
IF$_6^+$AsF$_6^-$ salt, 438
IF$_2^+$ ion, 434
IF$_6^+$ ion, 437
IF$_2^+$SbF$_6^-$ salt, 434
IF$_4^+$SbF$_6^-$ salt
to purify radon-contaminated air, 438
X-ray studies, 436
IF$_4^+(SbF$_6^-$)$_3$ salt, 437
IF$_4^+$Sb$_2$F$_{11}^-$ salt, X-ray studies, 436
IF$_6^+$SbF$_6^-$ salt, 438
I$_2^+$ ion, 428
disproportionation of, 429, 430
I$_3^+$ ion, 427–429
disproportionation of, 429, 430
I$_5^+$ ion, 427
disproportionation of, 430
valence bond structures of, 428
Imides, unsaturated, as alkylating agents, 592, 593

Imines
aromatic, hetero Diels–Alder reaction of, 689
cationic derivatives of, resonance forms, 199
cyclic, synthesis of, 685, 686
monofluorination of, 650
protonation of, 200

Iminium ions
acidic, 200
as intermediates, 604
nonacidic, 200
protonated, calculated structures of, 200
Increasing electron demand, see Gassman–Fentiman tool
Indane, formylation of, 629
Indan-5-ol, chlorination of, 656
Indanyl cation, X-ray studies, 145
Indoles
  hydroxylation of, 665
  trifluoromethylation of, 566
Indolines
  hydroxylation of, 665
  trifluoromethylation of, 566
2(3H)-Indolinones, formed in ring closure, 608
INDOR technique, 88, 226
Induction period, of cracking, 530
Infrared spectroscopy, see IR spectroscopy
Insertion
  into aliphatic σ-bonds, 636, 669, 670
  into C–C bond, 646, 676
  into C–H bond, 631, 636, 637, 642, 661, 676
  into Cr–C bond, 646
Intercalation, 72–74
Interhalogen cations
  heptaatomic, 437
  pentaatomic, 436
  triatomic, 433
Intracomplex mechanism, in formylation, 629
Iodine, one-electron oxidation of, 429
Iodine cations, 427
Iodine ion, blue species, 428, 429
Iodine(I) triflate, protosolvated, 657
5-Iodopentyne, protonation of, 376
para-Iodophenylphenyliodonium bisulfate, 361
N-Iodosuccinimide, in iodination, 657
Ion cyclotron resonance, 22, 410, 461
Ionic
  fluorination, with NO\(^+\), 644
  hydrogenation, 727
  role in coal liquefaction, 728
Ionic liquids
  in alkylation, 551, 560, 561, 574
  in formylation, 631
  in terpenoid cyclization, 712
  in transacylation, 616
Ion–molecule reactions, 22, 207, 210, 221, 461
[Ir(CO)\(_6\)]\(^{3+}\)(Sb\(_2\)F\(_{11}\)\(^-\))\(_3\) salt, X-ray studies, 455
IR–MPD, 102
IR photodissociation spectroscopy, 104, 124, 173, 314, 317, 363
IR spectroscopy, 69, 92
  in studying
    boreniun ions, 398
    carbocations, 104–106, 124, 140, 164, 209, 216, 238, 240, 243
    metal carbonyl ion, 457
    onium ions, 329, 354, 435, 449
Isatins
  alkylation with, 583
  polycondensation of, 746
I\(_2\)\(^+\)Sb\(_2\)F\(_{11}\)\(^-\) salt, X-ray studies, 429
I\(_5\)\(^+\)SbF\(_6\)\(^-\) salt, X-ray studies, 428
I\(_4\)\(^2+\)(Sb\(_3\)F\(_{14}\))\(_2\)SbF\(_6\)\(^-\) salt, X-ray studies, 430
Isoalkanes, formylation–rearrangement of, 631, 632
Isoborneol, protonation of, 707
IsoBu\(_2\)Al\(^+\) salts, 400
Isobutane, 524, 529, 552
  as alkylation agent
    of tert-butyl cation, 544, 546
    of butyl cations, 545
    alkylation of, with CH\(_3\)CH\(_2\)F–SbF\(_5\), 544
    carbonylation of, 624, 631, 632
  as cracking product, 540, 541
  H–D exchange of, 219, 220, 510, 512, 515
  involvement of carbenium ions in, 219
  hydride transfers from, 544
  ionization in HSO\(_3\)F–SbF\(_5\), 504
  isomerization of, 533, 534
  monochlorination of, 651
  oxygenation of, 661, 662, 668, 669
  protonation of, 222, 223
    in the presence of CO, 510
    reducing SbF\(_5\), 513
  regioselective deuteriation of, 516, 517
Isobutane–1-butene alkylation, 551, 552
Isobutane–2-butene alkylation, 551
Isobutane–isobutylene alkylation, 543, 544, 550
Isobutonium cations, calculated structures of, 222
Isobutyl alcohol, ether formation of, 700
Isobutyl cation, primary, 102, 103, 504
Isobutylene
  in alkylation, 543, 544, 548, 550
  oligomerization of, 745
Isodesmic reaction, 182, 266
Isoformyl cation, calculated structure of, 188, 189
Isolobal relationship, 211, 212, 213, 328
Isolongifolene, rearrangement of, to sesquiterpenes, 716, 717
Isomerization, 502, 503
  in adamantylation, 571, 573
  of alkanes, 517, 524
  within arenium ion, 567
  of bromophenols, 656
equilibria, 526
  of n-hexane, three-step process, 525, 527
  pivaldehyde, 725
Isopagodanes, two-electron oxidation of, 263
Isopentane
carbonylation of, 624
  in coal liquefaction, 728
  as cracking product, 540, 541
direct alkylation with CH$_3$CH$_2$F–SbF$_5$, 544
H–D exchange of, 511, 515
  ionization of, 504
  oxygenation of, 668
  potential–acidity diagram of, 522
  two-electron oxidation of, 520
Isopentyl alcohol, protonated, stability of, 315
Isoprene, Diels–Alder reaction of, 736
Isopropyl alcohol, alkylation with, 566
Isopropylation of aromatics, 574, 575
  protonated alkyl halide in, 574
Isopropylcarboxonium ion, 622–624
Isopropyl cation, 93, 94, 622, 623
  alkylation by, 545, 546
  alkylation of, 563
  chiral, 102
  $^{13}$C NMR shift of, 96
  $^{13}$C scrambling in, 545
  $^1$H NMR spectrum of, 95
  labeled, 101
  line–shape analysis of, 96
  rearrangement of, 101
  studies by cryogenic matrix isolation, 102
Isopropyl chloride, alkylation of aromatics with, 567, 570, 574, 575
Isopropylidene acetals, deprotection of, 704
1,2-O-Isopropylidene-β-D-fructofuranoses, transformation of, into spiroketals, 704, 705
Isopropyl sulfide, protonated, stability, 335
[(N-IsoPr$_2$)P(mesityl)]$^+$AlCl$_4^-$, X-ray studies, 419
IsoPrSH$_2^+$SbF$_6^-$ salt, X-ray studies, 333
Isoquinoline
  as alkylating agent, 592
  ionic hydrogenation of, 731
Isotope effect, in formylation, 628
Isotopic perturbation, 90, 227, 228, 234, 242, 243, 255, 272
Ketene, in acetylation of aromatics, 614
Ketene–diene cycloaddition, 736
Ketenes, protonation and silylation of, 191, 192
α-Ketoacids, alkylation with, 583
β-Ketoesters
  alkylation with, 584
  Michael addition of, 738
α-Ketoglutaric acid, alkylation with, 583
Ketoisophorone, rearrangement–aromatization of, 724
Ketones
  fluorinated, polycondensation of, 746
  oxygenation of, 674
  in oxygenation of alkanes, 670, 671, 673
  protonated, resonance forms of, 173
α-Ketonitriles, protonation of, 196
4-Ketopentanoic acid, diprotonated, 178
β-Ketophosphonates, alkylation with, 584
3-Ketosteroids, oxygenation of, 672
α-Ketosuccinic acid, alkylation with, 583
β-Ketosulphones, alkylation with, 584
Ketoximes, protonation of, 200
Kinetic factor, in alkane isomerization, 527
Kinetic studies, of methane exchange, in HF–SbF$_5$, 507, 508
Knorr cyclization, of N-substituted butyramides, 687, 688
Koch–Haaf
  acid synthesis, 116, 631
  reverse, 110
  reaction, 618
Kr$_2$F$_3^+$AsF$_6^-$ salts
  oxidation with, 437
  X-ray studies, 465
INDEX

KrF\(^+\) cation, 461
Kr\(_2\)F\(_3\)\(^+\) cation, 461
Kr\(_2\)F\(_3\)\(^+\)SbF\(_6\)\(^−\) salts oxidation with, 437
X-ray studies, 465
KrH\(^+\) cation, in mass spectrometry, 461
KrO\(_n\)\(^+\) cation, in gas phase, 465
β-Lactams, as acylating agents, 610
Lactide, cationic polymerization of, 746, 747
Lactones
formation of, 734
protonated, 178, 179
LAu\(^+\)BF\(_4\)\(^−\) salts, X-ray studies, 328
\[(LAu)\(_6\)C\]2\(^+\) complexes, X-ray studies, 213
Lewis acids
acid strength of, 8, 23, 24
in acylation of aromatics, 609
in coal liquefaction, 728
fluoride ion affinities of, 27
and polymeric resin sulfonic acids, 65
relative acidities of, 21, 23–27
Lewis superacids, 42–46
definition of, 7
intercalated into graphite, 72
Linear alkylbenzenes, 558
Line-shape analysis, 18, 19, 96, 225, 228, 229, 258
Longifolene, rearrangement of, to sesquiterpenes, 716, 717
Lower alkanes
alkylation of, by stable carbenium ions, 545–547
oligocondensation of, 543, 553
Macrocycles, iodonium-containing, 371
Magic Acid, 49, 84, 87, 104, 504. See also HSO\(_3\)F–SbF\(_5\)
 cracking ability of, 396
in generating
alkylcarboxonium ions, 186
carbodications, sulfur-stabilized, 194
diazonium ions, 386, 387
guanidinium dication, 201
hydronium ion, 312
H–D exchange in, 505, 509
in isomerization, 532
in oxygenation, 661–664, 668–672
protolytic condensation of methane in, 552
in protonating
alkanes, 504, 516
diaryl sulfoxides, 343
protonation in, 154, 174, 202
treatment of SiO\(_2\)–Al\(_2\)O\(_3\) with, 69
Magnetic circular dichroism measurements, 440, 444
Magnetic susceptibility measurements, 428

Mesitylene
alkylation of, 562, 565
formylation of, regioselective, 630
transnitration of, 643
Mesitylenium ion, X-ray studies, 127
Mesityl-vinyl cation, 136
Me₂Sn⁺FSO₃⁻ salt, 413
(MeS)₃⁺SbCl₆⁻ salt, X-ray studies, 346
Mes₂Si⁺(C₆F₅)₄B⁻ salt, 403
Mes₃Si⁺(1-H-CB₁₁Me₅Br₅)⁻ salt, X-ray studies, 404
(MeS)₂SMe⁺AsF₆⁻ salt X-ray studies, 347
Me₂SSMe⁺SbCl₆⁻ salt, X-ray studies, 346
Mes₃Sn⁺(C₆F₅)₃B⁻ salt, 414
[Mes₂TeSeAr]⁺SbF₆⁻ salt, X-ray studies, 355, 356
[Mes₂TeTeAr]⁺SbF₆⁻ salt, X-ray studies, 355, 356
Metal carbonyl cations, homoleptic, 453
Metal halides, graphite-intercalated, in ethylation of benzene, 557
Metal oxides, 69
modified
with Brønsted acids, 68, 533
with Lewis acids, 69, 533
Metal salts, 69
Metathetic silver salt reaction, 87, 195, 323
Methane
activation in HF–SbF₅, 210
alkylation by ethyl cation, 546
carbonylation of, 632
chlorination and chlorolysis of, 648
¹³C labeled, ethylation over solid superacids, 549
dication, see CH₄⁺
diprotonated, 212
electrophilic activation of, 506
ethylolation of, 546, 548, 549
fluorination of, 648–650
calculations, 649, 650
H–D exchange of, 507–509, 519
hydroxylation of, 663
ions, multiply-protonated, 212
nitration of, 637
oligocondensation of, 553, 670, 671
oxygennation of, 670, 671, 673
produced in reaction of butane, 534
protolytic condensation of, 552
protonation of, 207, 507
radical cations, 214, 215
reaction with D₂O-exchanged solid acids, 518
tetraprotonated, 214
triprotonated, 213
Methanesulfonic acid, sulfonylation with, 634
Methanesulfonyl chloride, sulfonylation with, 635
1,6-Methano[10]annulene, protonation of, 132, 154
Methano-bridged polycycle, synthesis by double alkylation, 607
Methanol, see Methyl alcohol
Methide shift, 531
Methine hydrogen, exchange of, 219, 220
Methenyl, 207. See also CH₃⁺ cation
calculated structures of, 208, 506, 507
fluxionality of, 208, 209, 506
intermediate or transition state, in exchange, 506
in protolytic condensation of methane, 552
solvated, 210
theoretical studies of, 506
4-Methoxyaryl methyl ketones, in transacylation, 616
para-Methoxybenzenediazonium ion, O-protonation of, 387
para-Methoxybenzydryl cations, as indicators, 15–17, 19, 58
Methoxydiazonium ion, 389, 390
2-Methoxyethyl benzoates, ionization of, 186
Methoxyhalo-carbenium ions, X-ray studies, 184
Methoxymethyl cation, 183
2′-Methoxy-5′-methyl-1,3-diphenylpropane, cyclization and rearrangement of, 721
2-Methoxynaphthalene, acylation of, 611
Methoxynaphthalenes, ionic hydrogenation of, 728
4-Methoxyphenyl cation, 140
1-(para-Methoxyphenyl)-2-(triisopropylsilyl)vinyl cation, 138
α-(para-Methoxyphenyl)-vinyl cation, 136
Methoxysulphonium ions, 344
2-Methoxy-1,7,7-trimethylbicyclo[2.2.1]hept-2-ylidium tetrafluoroborate, X-ray studies, 188
Methyl acetate
cleavage of, 735
dimethylation of, calculations, 183
distonic dication of, 735
gitonic dications of, 176, 177, 183
mono- and diprotonation of, 176
Methyl alcohol
alkylation with, 563, 564, 585
carboxylation of, 619
esterification with, 734
ether formation of, 700
protonated, 313
$^1$H NMR spectrum of, 314
stability of, 315
proton-bound dimer of, 314, 315
trans-1-Methylallyl cation, 124
para-Methylanisole, cyclization of, 720
Methylanisoles
bromination of, 656
rearrangement of, 589
Methylarylhalonium ions, 368
Methylation of aromatics, 563, 564
Methylazide, protonated, 387
Methyl benzoate, as acylating agent, 610
2-Methylbenzonitrile, electrochemical oxidation of, 753
9-Methylbenzonorbornenyl cation, X-ray studies, 134
Methylbicyclobutonium ions, 243
1-Methyl-1,4-bishomotropylium ion, 254, 262
2-Methylbutane, isomerization of, 533
2-Methylbutane-2-thiol, protonated, cleavage of, 332
Methylcarboranes, 107
3-Methyl[3-13C]pentane, isomerization of, 531
1-Methylcyclobutyl cation, rearrangement of, 116
Methylcyclohexane
carboxylation of, 625
as hydride donor, in coal hydroliquefaction, 543
Methylcyclopentane
carboxylation of, 624
as hydride donor, 631, 728, 729, 731, 732
ionization of, 504
isomerization of, 532, 533
Methylcyclopentyl ion, 504, 532, 624, 626
1-Methylcyclopent-1-yl cation
ESCA spectrum of, 235
generation of, 112
isotope scrambling in, 102, 112
Methylcyclopropane(s), protonated intermediates, 102, 103, 226, 529, 530
1-Methylcyclopropylmethyl cation, nonclassical, 241
Methyl diazonium ion, 384
calculated structures of, 385
Methyl difluorocarbenium ion, calculated structure of, 169
Methyl dithiobenzoates, preparation of, 633
S-Methyl dithiocarboxonium fluoroantimonates, preparation of, 632, 633
Methylenation
by ionic hydrogenation, 733
Peterson silyl-Wittig, 755
Methylenecyclobutenes, polysubstituted, ionization of, 259
Methylenecyclopropanes, 685, 686
Methylene diazonium ion, 384
2-Methylenetetramethyleneiodonium ion, 376
Methyleniminium cations, protonated, calculated structures of, 200
Methyl ethers, oxidative cleavage of, 641
Methyl E,E-farnesylic acid, cyclization of, 712
Methyl fluoride–antimony pentafluoride complex, see Methyl fluoroantimonate
Methyl fluoroantimonate, alkylation with, 363, 365, 366, 367, 368, 376, 377, 544, 632, 633
Methyl formate, protonated, X-ray studies, 175
Methyl (6Z)-geranyl farnesoates, selective cyclization of, 711
Methyl (R)-glycidate, alkylation with, 562
Methyl halides, oxidative carboxylation of, 620
4-Methyl[6]helicenium cation, 131
Methylhydridohalonium ions, 363
1-Methyl-5-hydroxypyrrolidin-2-one, in cyclialkylation, 606
7β-Methyl-14-isoestr-4-ene-3,17-dione, ionic hydrogenation of, 731
Methyl ketones
carboxylation of, 621
condensation of, 755
4-methoxyaryl, transacetylation with, 616
oxidative nitrolysis of, 645
in synthesis of homoallylic alcohols, 740, 741
Methyl migration, 408, 750
1-Methylnaphthalene, formylation of, 629
deuterated, isotope shift of, 238
Methylxonium ion, 735
2-Methylpentane
  cracking of, 539–541
  product distribution in, 540
  in isomerization, 527, 528, 531
  isomerization of, over solid superacids, 531
3-Methylpentane
  isomerization of, 530
  over solid superacids, 531
  in isomerization of \(n\)-hexane, 527, 528
Methylpentanes, isomerization and cracking of, 540, 541
3-Methyl-3-pentenyl ion, ethyl and methyl shifts in, 532
4-Methyl-2-pentyl cation, \(\beta\)-scission of, 540
2-Methylpropane, isomerization of, 533
2-Methylpropane-2-thiol, protonated, cleavage of, 332
Methylselenonium ion, 350
Methyl shift, 532, 726
1,2-Methyl shift, 227, 228, 707
\(\alpha\)-Methylstyrene, dimerization of, 754
Methylthiriane, protonation of, 335
1-Methylthiiranium ions, 2,3-disubstituted
  anionotropic rearrangements of, 337, 338
  X-ray studies, 337
Methyl thiobenzoates, preparation of, 633
\(S\)-Methyl thioarboxonium
  fluoroantimonates, preparation of, 632, 633
11-Methyltricyclo[4.4.1.0^{1,6}]undecyl cation, 116, 259
Methyl trifluoroacetate
  methylation of, 187
  protonation of, 178
3-Methyl-cis-verbanones, selective ring opening of, 715
\(Me_2XS^+\) salts, 341
MF\(_5\), in generating nonacidic imines, 201
Michael addition, 738
Microwave spectroscopy, 461
Migration, intramolecular, 573
Mixed acetal(s)
  synthesis of, 674, 679
  protonated, 741
Mixed acid, 636
Mixed anhydrides
  as acylating agents, 610
  \(CF_3SO_3NO_2\), nitration with, 638
  \(MeSO_2OTf\), sulfonylation with, 635
Mixed oxides, 63, 69
  modified with Lewis acids, 69
Mixed sulfates, 69
Mixed sulfoxides, 635
\([Mo(CO)_6(FSbF_5)]^+\)\(Sb_2F_11^-\) salt, 457
\([\{Mo(CO)_4]_2(cis-\mu-\mu-F_2SbF_4)_3^+\]_x(Sb_2F_11^-)_x\) salt, X-ray studies, 456
Molecular hydrogen
  H–D exchange of, 505
  reduction of carbenium ion with, 505
Monoalkylbenzenes, disproportionation of, 586, 587
\(\beta\)-Monocyclofarnesol and acetates, cyclo-
  rearrangement of, 710
\(\beta\)-Monocyclonerolidol and acetates, cyclo-
  rearrangement of, 710
Monodeuteromethane, H–D exchange of, 505
Monofluorosulfonium hexafluoroantimo-
  nate, 333
Mosher’s acid analogs, preparation of, 582
MRCI studies, 465
NaBH\(_4\)–triflic acid
  ionic hydrogenation with, 733
  methanation with, 733
NaBr–HF–SbF\(_5\), bromination with, 656
Nafion beads, 551, 577, 615, 744
Nafion-H, 66, 755
  in acylation of aromatics, 614
  in alkylation of
    alkanes, 551
    aromatics, 558, 563, 564, 565, 574–577, 585
  in azidobromination, 742
  in benzylolation, 560, 561
  in carbohydrate chemistry, 703, 704
  in carboxylation, 619, 620
  in cationic polymerization, 745
  in chlorination, 648
  in condensation, 755
  in cyclialkylation, 607
  in cyclization, 724
  in deacetylation, 616
  deactivation of, 551, 565
Nafion-H (Continued)
in decarboxylation, 616
in deformylation, 616, 617
in dehydration, 681, 698–700
in Diels–Alder reaction, 735, 736
in disproportionation, 586–589
embedded in MCM-41, 67
in Fries rearrangement, 618
in isomerization, 558, 586
in methylenation, 755
in nitration, 643
in oxygenation, 673, 674
in polyalkylation, 558
in protection group chemistry, 677–680
in rearrangement, 589
in ring opening, 696–698
in Ritter reaction, 743
in sulfonylation, 634
in synthesis of heterocycles, 694, 695
in transalkylation of aromatics, 587, 588
Nafion-H–HNO₃, nitration with, 643
Nafion-H–(HNO₃)Hg²⁺ nitrate, nitration with, 643
Nafion-H–SiO₂, in adamantylation, 577
Nafion-MCM-41
in alkylation, 566
in dimerization, 754
Nafion membrane, 66, 634, 643, 672, 673, 754
Nafion NR50
in acylation of aromatics, 615
in alkylation, 585
in Biginelli reaction, 694
in carbonylation, 619, 620, 626
in dehydration, 700
in dimerization, 754
in oxygenation, 673, 674
in phenol–dienone rearrangement, 722
in Ritter reaction, 744
Nafion resins
in esterification and ester cleavage, 734
in oxygenation, 672–674
Nafion SAC, 68
Nafion SAC-13
in acylation of aromatics, 615
in alkylation of
alkanes, 552
aromatics, 566, 585
in carbohydrate chemistry, 704
deactivation of, 552, 615
in dehydration, 700
in dimerization, 754
in esterification, 734
in oxygenation, 673, 674
in protection group chemistry, 678, 679
in ring opening, 698
in Ritter reaction, 744
in synthesis of heterocycles, 695
Nafion SAC-25
in acylation of aromatics, 615
in alkylation of alkanes, 552
Nafion SAC-40, 673, 684
Nafion SAC-80, 682
Nafion SAC catalysts, with Pt and Pd, in hydroxylation, 674
10% Nafion–silica, in alkylation of aromatics, 576
13% Nafion–silica, in alkylation of aromatics, 576, 577
Nafion–silica nanocomposites, 67
in acylation of aromatics, 614, 615
in alkylation of
alkanes, 551, 552
aromatics, 558, 559, 566, 576, 577
deactivation of, 551
in dimerization, 754
in esterification, 734
in Fries rearrangement, 618
in phenol–dienone rearrangement, 724
in synthesis of heterocycles, 682, 684
Nafion–SiO₂, in alkylation, 551, 577
NaN₃, as aminating agent, 659
Naphthacenyl cation, X-ray studies, 145
Naphthalene(s)
acylation of, 610, 618
alkylation of, 562, 566, 568, 576, 593
cyclialkylation of, 595
diprotonated, 154
hydroxylation of, 664
protonated, 664, 665
two-electron oxidation of, 163
Naphthalenium ion, ¹H NMR spectrum of, 126
Naphthol(s)
as alkylating agents, 591
alkylation of, 560
C-glycoside formation of, 704
Naphthol(s) (Continued)
  hydroxylation of, 666
  ionic hydrogenation of, 729
  in Ritter reaction, 743
Naphthoquinone, Diels–Alder reaction of, 736
Natural clay minerals, 69
Natural gas liquids, upgrading of, 529
Natural products
  cyclizations of 706
  oxygenation of, 666
  rearrangements of, 706
Nazarov-type cyclization, 597
NbF₅, 44
  intercalated into graphite, 74
N₅⁺ cation, X-ray studies, 389
Neighboring group participation, in
  glycosylation, 703
Neopentane
  C–C bond cleavage of, by protolysis, 542
  C–H bond protolysis, 542
  chlorination and isomerization of, 651
  ionization of, with C–C bond breaking, 504
  d₁₂-labeled, H–D exchange of, 505
Neopentyl alcohol, protonated, stability, 316
Nerol, rearrangement of, 708
Neutron diffraction, 311, 312, 329, 439
NF₄⁺AsF₆⁻ and PPHF, fluorination with, 649, 650
N₂F⁺AsF₆⁻ and PPHF, fluorination with, 649, 650
NF₄⁺BF₄⁻ salt, X-ray studies, 394
NF₃⁺ cation, 448
NF₄⁺SbF₆⁻ and PPHF, fluorination with, 649, 650
Ninhydrin, alkylation with, 583
Nitrilation, 636
ipso-Nitrilation, 639
Nitrenium ions, 415
  mesomeric structures of, 417
Nitric acid, nitration with, 638
Nitriles, in Ritter reaction, 685, 686, 705, 742, 743
Nitriilium ions, X-ray studies, 202
Nitrito onium ion, 393
S-Nitrosothiuronium ions, 345, 392
Nitroalkenes
  alkylation of benzene derivatives with, 556
  to form benzoazines, 690, 691
  9-Nitroanthracene, transnitration with, 643
Nitrobenzene, alkylation of, 581
α-Nitrocarbonyl compounds, as alkylating
  agents, 556
Nitrobenzene, oxidative, 645
Nitronium ion, 390
  insertion into aliphatic σ-bonds, 636, 637, 642
  as nitrating agent, 392
  protonated, 391, 392
Nitronium salts, 390
  ambident reactivity of, 345, 392, 640
  as initiators, in cationic polymerization, 744
  as nitrating agents, 636
  oxidative cleavage with, 641, 642
  as oxidizing agents, 640, 641
  preparation of, 636
N-Nitrosothiuronium salts, as transfer nitrating
  agents, 640
Nitrosothionium ion, 392
  halogen abstraction with, 645
  hydride abstraction with, 393, 644
  insertion into Cr–C bond, 646
  as nitrating agent, 645
  as nitrosating agent, 392
  oxidative cleavage with, 645
  as oxidizing agent, 645
  protonated, 393
  reactions induce by, 643, 644
Nitrosothionium salts, 393
  generating carbocations by, 111
  X-ray studies, 393
S-Nitrosothiuronium ions, 345, 392
NMR spectroscopy, 24, 28
  chemical shift
    for acidity measurement, 15, 16, 18, 27
    for hydrogen-bridged cations, 251, 252
    to study degenerate rearrangements, 89
dynamic, for exchange rate measurement,
  18
  rate exchange, for acidity measurement, 14
to study carbocations, 88
N₃NFO⁺SbF₆⁻ salt, calculated structure of, 449
Nα–Nβ rearrangement, 383, 386
N2O, O-methylation of, 389
NO\(^+\)BF\(_4\)\(^-\)/PPHF
desulfurative fluorination with, 646, 647
fluorination with, 393, 646
NO\(^+\)BF\(_4\)\(^-\) salt, 358, 360, 378, 383, 389, 393, 644
fluorination with, 393, 646, 647
as nitrating agent, 393
two-electron oxidation with, 358–360
NO\(_2\)\(^+\)/BF\(_4\)\(^-\)/C\(_0\)/PPHF
as nitrating agent, 636, 637
NO\(_2\)\(^+\)/BF\(_4\)\(^-\)/C\(_0\)/Sb\(_5\)F\(_{16}\)/C\(_0\) salt, X-ray studies, 383
NO\(_2\)\(^+\)/HSO\(_4\)\(^-\)/C\(_0\)/PPHF
ion, see Nitronium ion
NO\(_2\)\(^+\)/Sb\(_2\)Cl\(_6\)/C\(_0\)/PPHF
salt, as nitrating agent, 636
as nitrating agent, 636, 637
NO\(_2\)\(^+\)/Sb\(_2\)F\(_6\)/C\(_0\)/PPHF
salt, as nitrating agent, 636
7-Norbornadienyl cation, 260
Nonclassical ion(s), 85, 86, 87, 206, 229, 238, 239, 241, 242, 246 271
cleavage of, 542
reaction with NO\(_2\)\(^+\) salts, 642
7-Norbornenyl cation, 260, 261
2-Norborneols, in Ritter reaction, 743
1-Norbornenyl cation, 119
2-Norbornyl cation, 119, 228, 240, 642
dadditivity of chemical shift analysis for, 233
calculations, 238, 239
\(\sigma\)-delocalized nonclassical structure of, 238
equilibrating classical trivalent ions, 229
13C NMR spectra of, 232
ESCA spectroscopy of, 235, 236
exceptional stability of, 238
extra stabilization of, 238
Gassman–Fentiman tool, 235
1H NMR spectra of, 231
isotopic perturbation of, 234
line-shape analysis of, 229
NMR, temperature dependence of, 230–233
solid-state NMR of, 233, 234
stability of, 237, 238
studies by cryogenic matrix isolation, 233, 238
symmetrically bridged nonclassical
structure of, 229, 239
unsymmetrically bridged ions, 231
7-Norbornyl cation, 224, 239
nonclassical structure of, 240
studies by cryogenic matrix isolation, 240
Norpseudoephedrine derivative, in addition, 740, 741
A-Norsteroids, phenol–dienone rearrangement of, 723
Nortricyclymethyl cation, 244, 245
NS\(_2\)\(^+\)/Sb\(_2\)Cl\(_6\)\(^-\) salt, X-ray studies, 447
Nuclear decay, 224
Nuclear quadrupole resonance, 428
O\(_2\)\(^+\)/AsF\(_6\)\(^-\) salt, as oxidizing agent, 439
O\(_2\)\(^+\)/BF\(_4\)\(^-\) salt, 438
O\(^+\) cation, 438
OCNCO\(^+\)/Sb\(_3\)F\(_{16}\)/C\(_0\)/PPHF
salt, X-ray studies, 383
Octamethylnorbornadienediyldication, 265
Octane, composition of, in alkylations, 547
1,8-Octanediol, condensation–polymerization of, 745
Octane number(s), 502, 524, 525, 551
Octanoic acid, as acylating agent, 615
OH\(^+\) ion, incipient, in electrophilic oxygenation, 661, 666
Oil sand bitumens, hydrocracking of, 543
18O labeling, 740
Olefins, see Alkenes
Oleum(s), 442
acidity function values for, 48
in generating
acyl cations, 190
arylmethyl cations, 141
vapor pressure of, 48
Oleums–polysulfuric acids, 47
Oligocondensation, 543
of alkanes, 208, 553, 744
of alkenes, 744
oxidative, 670, 671
Oligomerization, of alkenes, 745
Oligosaccharides
  convergent total synthesis of, 701
  synthesis of, 703
One-electron oxidation, 129, 408, 411, 412, 414, 429, 530, 753
Onium ions, 311
  of group 15 elements, 381
ON(Me)CF₃⁺ ion, 450
¹⁷O NMR spectroscopy, 172, 190, 312, 314, 325, 329, 343, 392, 393, 661
O₂⁺PtF₆⁻ salt, 438, 439
  X-ray studies, 439
O₂⁺RuF₆⁻ salt, X-ray studies, 439
O₂⁺ salts, for collecting ²²²Rn
O₂⁺SbF₆⁻ salt, 439
O₂⁺Sb₂F₁₁⁻ salt
  decomposition of, 439
  photochemical synthesis of, 438
[Os(CO)₆]⁺BF₄⁻ salt, X-ray studies, 456
[Os(CO)₆]⁺(Sb₂F₁₁⁻)₂ salt, 455, 457
  X-ray studies, 455
[OsO₂(CO)₄]⁺(Sb₂F₁₁⁻)₂ salt, 455
OsO₃F⁺AsF₆⁻ salt, X-ray studies, 457, 458
OsO₃F⁺(HF)BF₄⁻ salt, X-ray studies, 458
OsO₃F⁺(HF)SbF₆⁻ salt, X-ray studies, 458
OsO₃F⁺SbF₆⁻ salt, X-ray studies, 457, 458
OsO₃F⁺Sb₂F₁₁⁻ salt, X-ray studies, 458
1-Oxa-3-azabutatrienium chloroantimonate, X-ray studies, 382
Oxacyclopentanes
  preparation of, 680
  ring-opening polymerization of, 746
Oxalic acid, protonated, X-ray studies, 175
Oxanorbornadiene, ring opening of, 697
Oxazolines
  as alkylating agents, 592, 593
  optically active, synthesis of, 692, 693
  [OxeF₃⁺(OTeF₅)₃]⁻ ion, 463
Oxenium ions, 424
O₂XeOTeF₅⁺ cation, 463
Oxides
  cyclization of, 693
  isomerization–polymerization of, 748
  as protonated intermediate, 684, 685
Oxidation, of hydrocarbons, 503
Oxidation dications, 162–164
Oxidative pathway, in alkane ionization, 511, 516
Oxime intermediates
  diprotonated, ring closure of, 691
  protonated, 556, 645
Oximes, oxidative cleavage of, 641, 645
Oximinothiolactones, formed in cyclialkylaation, 603
Oxindoles, Diels–Alder reaction of, 736
Oxirane cation, O-Alder reaction of, 326
Oxiranes
  alkylolation with, 563, 564
  protonation and cleavage of, 321, 322
  calculations, 321
  ring opening of, 696
Oxocarbonium ions, 506
Oxocarbenium ions, 506
Oxocarbon compounds, protonation of, 173, 174
Oxyfunctionalization, 660
Oxygen atom migration, 684, 685
Oxygenation
  of alkanes, 661
  of aromatics, 663
  of natural products, 666
  of perfluorinated cyclic compounds, 727
Oxygen heterocycles, ring opening of, 696
Oxygen insertion, into c-bond, in oxygenation with ozone 669, 670
Ozone
canonical structures of, 330, 331, 667
oxygenation with, 667
protonated, 661, 669–671

Ozonium ion, 330
as electrophilic oxygenating agent, 185, 669–671
proton affinity of, 331

Paal-Knorr synthesis, 596

Pagodadiene, two-electron oxidation of, 262, 263

Pagodane, two-electron oxidation of, 262, 263

Pagodane dication, 263, 265
X-ray studies, 263

Panasinsane, rearrangement of, 716

Parabanic acid, alkylation with, 583

Paraffin wax, cleavage to form tert-buty1 49, 504
lower-molecular-weight components, 539

207Pb NMR chemical shift, 414, 415

PCl4+ SbF6–/C0 salt, X-ray studies, 394

[Pd(CO)4]2+ (Sb2F11–/C0)2 salt, X-ray studies, 455

[Pd(MeCN)4]2+ (SbF6–/C0)/MeCN, X-ray studies, 458

5-Pentacyclo[6.2.1.13,6.02,7.04,10]dodecyl cation, 252

9-Pentacyclo[4.3.0.02,402,805,7]nonyl cation, 266

Pentacyclopropylethyl cation, 228

Pentafluorobenzene
alkylation of, 591
halogenation of, 657
Pentafluorobenzoic acid, aroylation with, 614
Pentafluorooxotellurate anion, see Teflate anion

Pentalene, dibenzoannulated, two-electron oxidation of, 163, 164

Pentamesityltritellurium cation, X-ray studies, 426

1,2,3,5,7-Pentamethyl-2-adamantyl cation, 257

Pentamethylcyclopentadiene, ionization of, 268

Pentamethylcyclopentadienyl cation, 268

trans-1,2,3,4,5-Pentamethyl-1-cyclopentenyl allylic cation, 268

Pentamethylenebromonium ion, 377

Pentamethylnitrobenzene, transnitration with, 643

n-Pentane
hydroisomerization of, 75
ionization of, 504
isomerization of, 524–526, 533
in C0F2n+1SO3H–SbF5, 529
rate limiting step in, 527
selectivity in, 532
proto1ytic cleavage of, 530
solubility in HF–SbF5, 524–526

2,4-Pentanediol, diprotonated, rearrangement of, 316

Pentanes, isomerization equilibria of, 526
1-Pentanol, protonated, stability of, 315

Pentaphenyltelluronium salts, hypervalent, 355
tert-Pentyl cation

13C NMR shifts of, 96

1H NMR spectrum of, 95
computational study of, 108
isotope scrambling in, 102
protonated, 223
X-ray studies, 107

Perchloric acid, 35, 36, 609, 748

Perchloroally1 cation, 169

Perchlorotriphenylmethyl cation, 169, 170

Perfluorinated cyclic compounds
complex transformations of, 727
oxygenation of, 675

Perfluorinated polymer resin acids, 66. See also Nafion-H

Aciplex, 67
Flemion, 67

Perfluorinated sulfonic acids, anchored to silica
in acylation of aromatics, 615
deactivation in, 615
in alkylation of aromatics, 559, 560
in esterification, 734
in polymerization, 750

Perfluoroalkanesulfonic acids, 38, 39, 40, 721
and Lewis acids, 54–56, 71
supported on zeolite HY, 576
tethered to silica surface, 67, 68

Perfluoroalkylaryliodonium ions, 367

S-Perfluoroalkylbenzothiophenium ion, 336
Perfluoroalkylcyclopentanols, dehydration of, 699
Perfluoroalkyl-substituted trialkyloxonium salts, 324
Perfluorobutanesulfonic acid, in acylation, 609
Perfluoroindane
as alkylating agent, 591
oxygenation of, 674, 675
Perhydroacenaphthene, isomerization of, 537
Perhydroindane, isomerization of, 532
Perhydro[2.2]paracyclophane, isomerization of, 538, 539
7-Perhydropentalenyl cation, 228
Permutit Q, 554
Peroxonium intermediates, 330
Peroxyacetic acid, synthesis of, 674
Peterson silyl-Wittig methylenation, 755
Petroleum fractions, higher boiling, upgrading of, 543
PF₅, 44
in preparation of NO₂⁺ ion, 636
PF₃H⁺SbF₆⁻HF salt, X-ray studies, 394
Ph₃C⁺BF₄⁻, hydride abstraction with, 187, 194
Ph₃C⁺(C₆F₅)₄B⁻
hydride abstraction with, 161, 398, 403, 405, 407, 415
one-electron oxidation with, 408, 412
in silylation, 188, 192, 327, 348
Ph₂CH₂–N₂O⁺ ion, 390
Ph₃C⁺PF₅⁻, hydride abstraction with, 420
Ph₃C⁺TFPB⁻, hydride abstraction with, 328
Ph₃C⁺TFPPB⁻, hydride abstraction with, 268, 272
Ph₃C⁺TSFPB⁻, hydride abstraction with, 408
Phenanthrenium ions, 130
Phenetole, rearrangement of, 589
Phenol(s)
acetylation of, 677
acylation of, 677
adamantylolation of, para selectivity in, 576
addition of, to alkenes, 738, 739
as alkylating agents, 591
alkylation of, 560, 564
ortho selectivity in, 564
bicyclic, phenol–dienone rearrangement of, 722
bromination of, meta selectivity in, 655, 656
cyclization of, 720
electrophilic halogenation of, 655
formylation of, 631
hydroxylation of, 665
nitrozation of, 644
protonated, in alkylation of aromatics, 593
protonation of, 317, 655, 656
ring-alkylated, formation of, 589
in Ritter reaction, 743
triarylalsylation of, 677, 679
Phenol–dienone rearrangements, 722, 728
Phenol ethers
cyclization of, 720
hydroxylation of, 665
protonated, in alkylation of aromatics, 593
Phenolic esters, Fries rearrangement of, 618
Phenolic ethers, phenol–dienone rearrangement of, 722
Phenoxymethyl cation, 183
Phenylacetyl chloride, as acylating agent, 615
2-Phenyladamant-2-yl cation, X-ray studies of, 115
Phenylalkanols, cyclization of, 599, 600
3-Phenyllallyl alcohols, alkylation with, 561
Phenylation, 660
Phenylaminodiabenzonium ion, protosolvated, 660
Phenylclosazine, phenylation with, 660
Phenylchloromethyl cations, 169
(Z)-α-Phenyl cinnamic acid, protonated, 611
Phenyl(cyano)iodonium ion, 365
1-Phenylclobutyl cation, 116
7-Phenyl-2,3-dimethyl-7-norbornenyl cation, X-ray studies, 260
2-Phenyl-1,3-dioxane, benzylation with, 579, 580
2-Phenyldodecane, selectivity of, in alkylation, 559
2-Phenylethanol, cyclization and rearrangement of, 599
β-Phenylethyl cations, 132, 133
1-Phenylfluoroethyl cation, 167, 168
Phenyl formate, deacylation of, in hydroxylation, 665
Phenyl group, charge delocalization into, 150, 151
1-Phenyl-1H-indenes, formed in cyclodehydration, 596
Phenylpropanes, substituted, aromatic cyclization of, 718, 719
3-Phenylpropanols, rearrangement and cyclization of, 600
1-Phenyl-2-propen-1-ones, cyclodehydration of, 597, 598
Phenylpropiolic acid, nitration of, 642
Phenylpropionyl chloride, as acylating agent, 615
Phenylpyruvic acid, alkylation with, 583
Phenylsulfenium cation, calculated structure of, 426
Phenylsulfides, desulfurative fluorination of, 646, 647
Phloroglucinol, as alkylating agent, 593, 594
Phosphaferrocenes, acylation of, 610, 611
Phosphanyl phosphonium ion, X-ray studies, 420, 421
Phosphenium ions, 417
cyclic, X-ray studies, 418, 419, 420
with donor ligands, 419, 420
ferrocenyl-stabilized, 419
with homoatomic P=P coordination, 421
iminium ion character of, 418
31P NMR chemical shift of, 418, 419, 422
role of dialkylamino groups, 417
Phosphines, tertiary, oxidation of, 641, 642
Phosphirenylium ions, 422, 423
Phosphites, as glycosyl donors, 702
[(Ph3PAu)3Se]2+PF6− salt, X-ray studies, 357
[(Ph3PAu)3S]PF6− salt, X-ray studies, 348, 349
[(Ph3PAu)3S]2+(TFO)2− salt, X-ray studies, 349, 350
[(Ph3PAu)4Te]2+ dication, 357
[(Ph3PAu)3Te1+PF6− salt, X-ray studies, 357
Ph2(PMe3)SbPF6− salt, 424
pH scale, 3
Phosphorus compounds, protonation of, 395
Ph2Se6+AsF6−SO2 salt, X-ray studies, 355
PH4+TaF6− salt, 395
Pictet–Spengler cyclization, 604
Pinacolone rearrangement, 316, 698
β-Pinene, protonation of, 707, 708
Piperidinones, stereoselective ring closing of, 604, 605
Piperidinones, alkylation with, 581
3-Piperidin-1-yl-propionaldehyde, dioxolane of, 580
Pivalaldehyde, isomerization of, 725
Pivalic acid, 518
Pivaloyl cation, 110
Plumbanorbornyl cation, 414
Plumbycations, bisalkene complexes, 414, 415
Poly(arylenesulfonium) salts, 336
Polyatomic cations, 426
of group 16 elements, 438
Polycations, 147
Poly(ethyleneimine)/HF complex, in alkylation, 551
Polyfluoronitrobenzenes, nitration of, 637, 638
Polyhalomethane–nAlX₃, halogenation with, 651
Polyheteroatom cations, 445, 447, 448
Polyisoprene, cyclization of, 716
Poly lactides, 746
Polymeric resin sulfonic acids, complexed with Lewis acids, 65
Polymerization, 744
Polymethylaceto phenones, in transacetylation, 615, 616
Polymethylene oligomer, 553
Polyols, transfer nitration of, 640
Polysaccharides, cleavage of glycosidic linkages in, 705, 706
Polyselenium cations, 441
Polystyrene nanospheres, functionalization of, 660, 675
Polystyrenes, sulfonated, 554
Polysulfur cations, 439
Polytellurium cations, 444
Polytopal rearrangement, 208
Polytrityl cations, 152
Poly(4-vinylpyridinium)/HF complex (PVPHF), 41
in alkylation, 551
Positional selectivity (ortho/para ratio), in competitive acylation, 609
alkylation, 560, 565, 571, 572, 574
electrophilic oxygenation, 675
formylation, 629
nitration, 638
phenylamination, 660
Potassium nitrate, nitration with, 638
Potentiometry, 25
Pourbaix’s type diagram, 522
Pregnan-3,20-diones, isomerization of, 717, 718
Prins reaction, 683, 693
Propane
as alkylation agent, 591
alkylation of, by carbocations, 545, 546, 548, 549
bromination of, 651
carbonylation of, 621–624
protolytic cleavage in, 622, 623
selectivity in, 623, 624
C₆ isomer distribution, in alkylation of, 545
¹³C labeled, 511
as cracking product, 540, 541
H–D exchange in, 514, 515
hydroxylation of, 663
ionization of, 511
monochlorination of, 651
oligocondensation of, 553
oxygenation of, 673
protonation of, 218, 219
Propane-1,3-diol, 579, 607, 678
1,2-Propanediol, diprotonated, rearrangement of, 316
Propanol, see n-Propyl alcohol
1-Propargylbenzotriazole, as alkylation agent, 594
Propargyl cations, 134, 135
Propargyl complexes, cationic dicobalt, 204
Propene
alkylation of adamantane with, 548
in cracking, 540, 541
Propionaldehyde, protonated, 316
Propargyl benzotriazole, as alkylation agent, 594
Propargyl cations, 134, 135
Propargyl complexes, cationic dicobalt, 204
Propene
alkylation of adamantane with, 548
in cracking, 540, 541
Propionaldehyde, protonated, 316
Propargyl complexes, cationic dicobalt, 204
Propene
alkylation of adamantane with, 548
in cracking, 540, 541
Propionaldehyde, protonated, 316
Propargyl benzotriazole, as alkylation agent, 594
Protection group chemistry, 676
Proto adamantyl cation(s), 245, 257, 258
Protoformyl dication, calculate structure, 188
Protolytic cleavage of C–C bonds, 503
of C–H bonds, 503, 623, 624
Protolytic cleavage of C–H bond, 510
of pentane and hexane, 530
Proton, generation in oxidative pathway, 516
Protonated alkyl halide, in isopropylation of aromatics, 574
Protonated intermediates in cyclialkylation, 600, 601
in oxidative nitrolysis, 645
in ring closure, 726
Protonation of alkanes, in electrochemical oxidation, 520, 522
of σ-bond, 542
of C–C bonds, 503
of C–H bonds, 503
reversible, 503, 510, 511, 513, 516
ipso-Protonation, 131, 579, 750
Proton exchange, 101, 197, 313, 314, 329, 516
Protonitronium dication, calculations, 391, 392
gas-phase studies, 392
in nitration, 637
17O NMR spectrum of, 392
Protonitrosonium dication, 393
17O NMR spectrum of, 393
Proton shielding, in Se and Te ions, 351
Proton transfer, 685, 748, 749
Protosolvation, 327, 391, 501, 623, 637, 660, 725
Pseudoionone, cyclization of, 721
[Pt(CO)4]2+ (Sb2F11−/CO)2 salt, X-ray studies, 455
[Pt(MeCN)4]2+ (SbF6−/CO)2/MeCN, X-ray studies, 458
Pyramidal cations, 267, 269
intermediate, 224
Pyramidalization, 115, 118, 134
Pyrazolecarboxaldehydes, alkylation with, 581
Pyrenium cations, 130
Pyridine, absorbed, IR spectroscopy of, 68, 69, 533
Pyridinecarboxaldehydes, alkylation with, 581
Pyridinium poly(hydrogen fluoride) (PPHF), 41
in alkylation, 551
in nitration, 640
in oligosaccharide synthesis, 704
Pyrroles, N-substituted, acylation of, 610
Pyrrolinones, aryl-tethered, cyclization of, 606
Pyrrolyium salts, 181
Quantum mechanical calculations, 93
4-(3H)-Quinazolines, synthesis of, 694, 695
Quinidine, cyclization of, 689
Quinidine dihydrochloride, difluorination of, 653
Quinidinone, monofluorination of, 652
Quinine cyclization of, 689, 690
polyprotonated, 689, 690
Quinone acetate difluorination of, 653, 654
oxygenation of, 666
Quinoline as alkylating agent, 592
ionic hydrogenation of, 731
Quinuclidone, alkylation with, 581
Radiolysis, 224
Raffinate II, alkylation of, 552
Raman spectroscopy, 25, 28, 92
data for carbocations, 104–106
in studying halogen cations, 428, 432, 434–438
N3NFO+ ion, 449
Te42+ dication, 444
[RC≡NKrF]+ AsF6− salt, 465
[RC≡NXeF]+ AsF6− salt, 464
RCoO2–2AlBr3, in oxidative coupling of C5–C6 cycloalkanes, 553
(R5C5)Si2+, salts, X-ray studies, 409
Rearrangement(s) in alkylation of aromatics, 561, 562
anionotropic, 337, 338
of 9-barbaraly1 cations, 253–255
bridge flipping, 260
of sec-butyl cation, 225, 226
of carbocations, 101, 116, 118, 315, 511, 523, 531, 699
of C5H9+ ions, 224
of C10 hydrocarbons, 535, 536
circumambulatory, 150
Cope, 725
degenerate, 116, 244, 256, 257
dications, 154
Rearrangement(s) (Continued)  
and formylation, 631, 632
Fries, 618
of natural products, 706
\( {N}_a–{N}_b \), 383, 386
of perfluorinated cyclic compounds, 727
phenol–dienone, 722, 728
of phenolic ethers, 589, 599, 600
of phenylalkanols, 599, 600
pinacolone, 306, 698
polytopal, 208
of protonated diols, 316, 317
of resin acids, 717, 718
of ring halonium ions, 366, 377
Schmidt, 751
skeletal, 511, 523, 531
of terpenes, 708, 710, 715, 716
Redox couples, standard potential of, 523
\( \text{Re}_2\text{O}_4\text{F}_5 \) cation, X-ray studies, 457
\( \text{ReO}_2\text{F}_2(\text{MeCN})_2 \)^+\text{SbF}_6^- salt, 458
Repulsive interactions, charge–charge, 501
Resin acids, rearrangement of, 717, 718
\[ \text{Rh(CO)}_4 \]^+\text{1-Et-CB}_{11}\text{F}_{11}^- \text{ salt, 456} \]
X-ray studies, 455
fac-\( \text{Rh(CO)}_3(\text{FSO}_3)_3 \) complex, 454
\[ \text{Rh(CO)}_4 \]^+ salts, 456
Rhodizonic acid, tetraprotonated, 174
Ring closure
of dihydroxy compounds, 681
of enol ethers, 682
Ring contraction, in esterification, 734
Ring opening
of cycloalkanes, 542
of oxygen heterocycles, 696–698
Ritter products, 685, 686
Ritter reaction, 644, 705, 743, 753
Ritter-type reaction, 742
\( ^{222}\text{Rn} \) in uranium mines, collecting of, 439
Rotational barrier, 124, 137, 138, 142, 204
Rotaxanes, synthesis of, 735
\( (\text{R}_3\text{PAu})_2\text{S}^+\text{BF}_6^- \) salts, X-ray studies, 349
\[ [(\text{R}_3\text{P})\text{Au}]_2\text{X}]^+\text{BF}_4^- \text{ salts, 459} \]
\[ \text{Ru(CO)}_6 \]^+\text{BF}_4^- salt, X-ray studies, 456
\[ \text{Ru(CO)}_6\text{S}^2+(\text{Sb}_2\text{F}_{11})^- \text{ salt, X-ray studies, 455} \]
\( \text{R}_2\text{XS}^+ \) ions, 341
\( \text{S}_4\text{S}^{2+}(\text{AsF}_6^-)_2 \) salt, X-ray studies, 440
\( \text{S}_8\text{S}^{2+}(\text{AsF}_6^-)_2 \) salt, X-ray studies, 440
\( \text{S}_{16}\text{S}^{2+}(\text{AsF}_6^-)_2 \) salt, 441
\( \text{S}_{19}\text{S}^{2+}(\text{AsF}_6^-)_2 \) salt, X-ray studies, 441
Sabine, protonation of, 707, 708
Saturated hydrocarbons, see also Alkanes
conversion of, 501
hydrogen abstraction from, 110
monohalogenation of, 651
\[ [(\text{SAu}_2\text{dpff})]\text{[Au(C}_6\text{F}_5)_2]\]^+\text{TFO}^- \text{ salt, X-ray studies, 349} \]
\( \text{SbCl}_5 \), 382, 447, 449
in generating
carbosulfonyl ion, 194
\( \alpha-\pi \)-complexed organometallic cation, 205
cyclic carboxonium ions, 185, 186
\( \text{SbCl}_4^+\text{Sb}_2\text{F}_{11}^- \) salt, X-ray studies, 394
\( \text{SbF}_5 \), 42, 95, 439, 442, 444, 451, 727
in benzylations, 561
concentration effect of, 510–515, 525, 526, 528, 629, 634
dehalogenation with, 187
fluorinated, 74
in generating
acylium ions, 191
alkylcarbenium hexafluoroantimonates, 589
alkyl cations, 94, 95, 109, 110, 112, 114, 116, 120, 121
allyl cations, 124
arylmethyl cations, 141, 146
bridgehead cations, 117, 119
cage dications, 262, 263
chlorocarbolin cation, 189
cubylidiacyclium ion, 191
dications, 149, 157
enium ions, 416
halocarbolin cations, 189
halogen cations, 428, 429, 430, 434
halonium ions, 363, 365, 366, 372–378
homoaromatic cations, 261, 263, 265, 267
metal carbonyl cations, 457
methoxyhalo-carbenium ions, 184
2-norbornyl cation, 229–232
onium ions, 330, 341, 343, 344
pagodane dication, 263
polyatomic cations, 439
pyramidal dications, 270, 271
silylbicyclobutonium ions, 244
thiouronium dication, 197
triaxane cations, 245, 246
SbF₅ (Continued)
intercalated into
Al₂O₃, 74
graphite, 73, 74
leaching of, 74, 533, 535, 558
in oxygenation, 674
polymeric structure of, 43
in preparation of NO₂⁺ ion, 636
reduction of, 513, 535
superelectrophilic species, detected in, 727
treatment of SiO₂–Al₂O₃ with, 70
two-electron oxidation with, 161, 163, 164
SbF₅–Al₂O₃, in isomerization of alkanes, 534
SbF₅–graphite intercalate, 73
in chlorination, 648
in cracking of alkanes, 539
in ethylation of benzene, 557
in ethylation of ¹³CH₄, 549, 550
in isomerization of alkanes, 531, 532
selectivity in, 532
in oxidative carboxylation, 620
rapid deactivation of, 74, 532
SbF₅s, retained in, 535
in skeletal rearrangement, 531
in transethylation of aromatics, 587, 588
SbF₅–SiO₂, in isomerization of alkanes,
534
SbF₅–SiO₂–Al₂O₃, in isomerization of
alkanes, 533, 534
SbF₅–SiO₂–TiO₂, in isomerization of
alkanes, 533
SbF₅–TiO₂, in isomerization of alkanes, 534
SbF₅–TiO₂–SiO₂, in isomerization of
alkanes, 534
SbF₅–TiO₂–ZrO₂, in isomerization of
alkanes, 534
SbH₄⁺SbF₆⁻ salt, 395
S⁻Br⁺SbF₆⁻ salt, X-ray studies, 453
SbX₄⁺[Sb(OTeF₅)₆]⁻ salt, X-ray studies,
394
S₅⁺ cation, 440
Schmidt reaction, 688
Schmidt rearrangement, 751
β-Scission, 539–542
S₁Cl₃⁺AsF₆⁻ salt, X-ray studies, 451
S₄⁺ dication, 439

Sulfuranyl dication, X-ray studies, 339
Sulfuric acid
dissolving elemental selenium in, 441
in hydroaminaton, 685
in Koch–Haaf reaction, 619
in preparing
HB(HSO$_4$)$_4$, 47
sulfated metal oxides, 68, 69
protonated ethers, cleavage in, 319, 320
sulfonation with, 633
Superacidity scales, calculated, 22
Superacids
binary, 10, 47
Brønsted, 35
in carbohydrate chemistry, 700
conjugate Brønsted–Lewis, 10, 47
definition of, 6, 7, 24
in heterocyclic chemistry, 680
immobilized, 71
primary, 10, 35
in protection group chemistry, 676
ternary, 10, 62
types of, 9
Superelectrophiles, 83, 501
Superelectrophilic activation, 501, 582
Superelectrophilic dications, 193, 194, 687, 698
in alkylation, 555, 559, 581, 582
in formation of benzoazines, 692
in ionic hydrogenation, 729, 730, 733
Superelectrophilic metal cations, 455
Superelectrophilic species, 657, 725
Superelectrophilic trications, 555, 556, 603, 722, 729
TaF$_5$, 44, 430
in ethylation of $^{13}$CH$_4$, 549
intercalated into graphite, 74
TaF$_5$–Al$_2$O$_3$, in ethylation of $^{13}$CH$_4$, 549, 550
Tailbiting mechanism, in ring-opening polymerization, 747, 748
Tandem ring opening/ring closing, 685
Te$_2$O$_2$F$_0^+$ cation, X-ray studies, 457
$^{99}$Te NMR, 457
Te$_4$$^{2+}$AlCl$_4^-$ salt, X-ray studies, 444
Te$_4$$^{2+}$AlCl$_4^-$ salt, X-ray studies, 444
Te$_6$(AsF$_6$)$_4$$^{2-}$ AsF$_3$, X-ray studies, 445
Te$_4$$^{2+}$(AsF$_6$)$_2$ salt, 444
Te$_7$$^{2+}$(AsF$_6$)$_2$ salt, X-ray studies, 445
Te$_6$(AsF$_6$)$_4$$^{2-}$ SO$_2$, X-ray studies, 445
Te$_n$$^{n+}$ cation, 445
Te$_2$O$_2$F$_0^+$ cation, 444
Te$_4$$^{4+}$ cation, 445
Te$_6$$^{6+}$ cation, 445
Te$_8$$^{8+}$ cation, 445
TeCl$_3$$^{2+}$AsF$_6$$^{2-}$ salt, 356
Te$_6$$^{6+}$ cluster cation, 445
Te$_4$$^{2+}$ dication, 444, 446
Teflate anion, 171
TeF$_3$$^{+}$Nb$_2$F$_{11}^-$ salt, X-ray studies, 356
Te$_4$$^{2+}$(FSO$_3$)$_2$ salt, 444
TeI$_4$$^{+}$AsF$_6$$^{-}$SO$_2$ salt, X-ray studies, 357
Telluranyl dication, X-ray studies, 355
Telluronium ions, 350
Telluronium tetrafluoroborates, X-ray studies, 354
Temperature programmed desorption, for acidity measurement, 28, 29
$^{125}$Te NMR chemical shifts, 353–355, 359, 426
Terpenoids, 706
Terpenoids, acids and esters, selective cyclization of, 711
bicyclic ethers, synthesis of, 709
dienols, cyclization of, 710
phenylsulfones, selective cyclization of, 711
trienols, cyclization of, 710
trienone, cyclization of, 709
Terpenol acetates, selective cyclization of, 711
Terpenols, selective cyclization of, 711

$\alpha$-Terpineol, protonation of, 707, 708

Te$_3$S$_3$$^+$ (AsF$_6$/C$_6$)$_2$ salt, 446
Te$_4$$^+$ (SbF$_6$/C$_6$)$_2$ salt, X-ray studies, 444
Te$_4$$^+$ (Sb$_2$F$_{11}$/C$_6$)$_2$ salt, 444
Te$_2$Se$_4$$^+$ (AsF$_6$/C$_6$)$_2$ salt, 446
Te$_3$Se$_6$$^+$ (AsF$_6$/C$_6$)$_2$ salt, X-ray studies, 446

Te$_{1.5}$Se$_{5.5}$$^+$ (AsF$_6$/C$_6$)$_2$ salt, 446
Te$_2$Se$_8$ (AsF$_6$/SO$_2$)$_2$, 446
(Te$_6$$^{4+}$)(Se$_8$$^{2+}$)(AsF$_6$/SO$_2$)$_2$, 443
X-ray studies, 445

trans-Te$_2$Se$_2$$^+$ dication, 446

Te$_2$Se$_8$$^+$ dication, X-ray studies, 446
Te$_3$Se$_{10}$$^+$ dication, 446
Te$_2$Se$_4$$^{2+}$ (SbF$_6$/C$_6$)$_2$ salt, 446
Te$_2$Se$_4$$^{2+}$ (Sb$_2$F$_{11}$/C$_6$)$_2$ salt, 446
Te$_3$Se$_3$$^{2+}$ (AsF$_6$/C$_6$)$_2$ salt, 446
Te$_3$Se$_3$$^{2+}$ (SbF$_6$/C$_6$)$_2$ salt, 446
Te$_2$Se$_6$$^{2+}$ (SbF$_6$/C$_6$)$_2$ salt, X-ray studies, 446

Te$_2$Se$_2$$^{2+}$ (Sb$_{14}$F$_{14}$) (SbF$_6$/C$_6$)$_2$ salt, X-ray studies, 446

Te$_2$Se$_4$$^{2+}$ (Sb$_{14}$F$_{14}$) (SbF$_6$/C$_6$)$_2$ salt, X-ray studies, 446

(2S$_2$Se$_2$$^{2-}$ (Te$_2$Se$_4$$^{2-}$) (AsF$_6$/C$_6$)$_2$) (SO$_2$)$_2$, 446
Te$_4$$^{2+}$S$_2$O$_{10}$$^{2-}$ salt, 444
Tetraanisylethylene 1,2-dication, 155, 156
X-ray studies, 155

9,9,10,10-Tetraaryldihydrophenanthrenes, oxidation of, 151
Tetraarylpinacols, to give condensed aromatics, 698

Tetrabenzo[5,5.5]fulvalene dication, 157
Tetra-tert-butyldihydrophosphacubane, protonation of, 396

Tetracation, tetrahedrally arrayed, 151
1,3,5,7-Tetradeteroadamantane, formylation of, 631

Tetrafluoroboric acid, see also HBF$_4$ and HF–BF$_3$

in generating polytrityl cations, 152
1,1,2,2-Tetrafluoroethanesulfonic acid, 40
in acylation, 611
in alkylation of aromatics, 559
supported on silica, 72, 559

Tetrahaloneopentanes, 375

Tetrahiomethane tetracation, He$_4$C$_4$$^+$, calculations, 465

Tetrahydrofurfuryl ions, for acidity measurement, 21

Tetrahydrofuran cationic polymerizations of, 745, 747
protonated, 747

Tetrahydrofuranyl ions, for acidity measurement, 21

Tetra(hydrogen sulfato)boric acid–sulfuric acid, 47

Tetrahydroisoquinoline derivatives, formed in cyclialkylation, 604

Tetrahydropyrans, stereospecific synthesis of, 682, 683

Tetrahydropyranly (THP) ethers, 677–679

Tetrahydroquinoline alkylation of, 593
bromination of, 656
hydroxylation of, 665

Tetrahydroxyphosphonium hexafluoroantimonate, X-ray studies, 395

1,1,3,3-Tetrakis(alkylamino)allyl cation, X-ray studies, 203

Tetrakis(dimethylamino)ethylene dication, 202, 203

Tetralin(s)
formed in cyclialkylation, 595, 600, 607
formylation of, 629
hydride donor, in ionic hydrogenations, 728

Tetralones, formation of, in ionic hydrogenation, 729

Tetramantyl cations, 119
1,3,5,7-Tetramethyl-2-adamantyl cation, 257
degenerate rearrangements of, 257
line-shape analysis of, 258
nondegenerate rearrangement of, 258
static σ-bridged structure, 257, 258
static protoadamantyl cation, 257
2,2,3,3-Tetramethylbutane
formation of, in direct alkylation, 546
ionization of, with C–C bond breaking, 504
2',6,6'-Tetramethyl-4,4'-di-tert-butyldiphenylmethane, 588
1,2,3,4-Tetramethyl-5,6-dinitrobenzene,
formation of, 639
2,2,5,5-Tetramethyltetrahydrofuran,
cyclialkylation with, 595, 596
2,2,5,5-Tetramethyltetramethylenechloronium ion, 376
1,2,4,7-anti-Tetramethyl-2-norbornyl cation,
X-ray studies, 238
Tetramethyloxirane cation, O-methylated,
calculated structures of, 327
2,2,5,5-Tetramethyltetrahydrofuran,
cyclialkylation with, 595, 596
2,2,5,5-Tetramethyltetramethylenechloronium ion, 376
Tetraphenylethylene 1,2-dication, 155
Tetraphosphatricyclodiene, protonation of, 397
Tetrasubstituted ethylenes, two-electron oxidation of, 155
Te2WOBr5, 445
TFA, see Trifluoroacetic acid
Theoretical calculations, for acidity,
22, 23
Thermodynamic factor, in alkane isomerization, 527
1-Thia-3-azabutatrienium chloroantimonate,
X-ray studies, 382
Thiane-3,3,5,5-d-4, protonation of, 334
Thianthrene, alkylation of, 336
Thiazyl cation, NS+, 447
Thiethanium ion, 338
Thiethium ion, 338
Thirane, protonation of, 335
Thirane-1-oxide, protonation of, 335
Thiranium ions,
involved in glycosylation, 703, 704
isomerization of, 338
X-ray studies, 337
Thiirenium ions rearrangement of, 338
Thioacetilation, 676, 677
Thioacetals, oxidative cleavage of, 641, 642
Thiobenzoyl cations, 195
Thiocarbenium ions, 194
Thiocarbonate(s)
cyclic, ring-opening polymerization of, 747
protonation of, 192
Thiocarboxylic acids, protonation of, 192
Thioformaldehyde, diprotonated, calculated structure of, 193, 194
Thioketals, oxidative cleavage of, 645
Thioketones, protonation of, 193
Thiols
protonated, cleavage of, 332, 333
protonation of, 110, 192, 332
Thionitronium ion, NS2+, 447
Thionyl chloride, sulfonylation with, 635
Thiophene, alkylation of, 335, 336
Thiophenols, acylation of, 677
Thiosulphonium ions, 347
Thiourea, protonation of, 197, 198
Three-component synthesis, 694, 695
TiO2–SiO2, in isomerization of alkanes, 534
α-Tocopherol, synthesis of, 684
Toluene
acylation of, 611, 618
competitive, 609
adamantylation of, 567, 570–572, 574, 576, 577
para selectivity in, 576, 577
alkylation of, 563, 565, 566, 568–570, 575, 576, 585, 586, 589, 590
competitive, 560, 565, 571, 572, 574
temperature dependence of, 563
cyclialkylation of, 595
formylation of
competitive, 627, 628
regioselective, 630
with high para yield, 630
Toluene (Continued)
monohydroxylation of, competitive, 675
nitration of, competitive, 638
phenylamination of, competitive, 660
transnitration of, 643

para-Tolyl chloride, as acylating agent, 611
Tool of increasing electron demand, 91.
See also Gassman–Fentiman tool

Transacylation, 615, 616
Transalkylation
of aromatics, 587
of dialkylsulfides
with dialkylhalonium ions, 335
with trialkyloxonium ions, 335
of oxonium ions, 323, 324
Trans-tert-butylation, 587–589, 681
Trans-debenzylation, 588
Transesterification, 734
Transfer hydrogenation, ionic, 731, 732
Transfer nitration, 640
Transnitration, 643
1,2,3-Triacetoxypropane, transesterification
of, 734
Trialkyl(aryl)silanes, fluorination of,
647
Trialkylboron–triflic acid, ionic hydrogenation with, 733
Trialkyloxonium salts
alkylation with, 327, 382
perfluoroalkyl-substituted, 324
pyramidal structure, 326
syntheses of, 323, 324
X-ray studies, 324
Trialkylsiloxonium fluorosulfates, 352
O-Trialkylsilylation, 677
Trialkylsilyl ethers
cleavage of, 679
oxidation of, 645
transformation of, into ethers, 680
γ-endo-Trialkylsilyl substituent, stabilization effect of, 244
Triamantane
formation of, 536
ionization of, 119
9-Triamantanol, ionization of, 119
Triamantyl cations, 119
Triangulenium cations, X-ray studies, 144
Triarylarsines, oxidation of, 642
Triarylmethane–triarylmethylum
naphthalene cations, X-ray studies, 144
Triaryloxonium ions, stability of, 325
Triarylphosphonium salts, in photoinitiated cationic polymerization, 748
Triaryl stibines, oxidation of, 642
Triarylsulphonium salts, in photoinitiated cationic polymerization, 748
Triaxane-2-methyl alcohol, ionization of, 245
Triaxane-2-methyl cation, 245
Triazolinium ion, X-ray studies, 416, 417
Tribromomethylation, 591
Tribromomethyl cation, X-ray studies, 171
Tributylstannanes, 369
O-Tributylstannyl ethers, oxidation of, 645
Tricationic intermediates, in cyclalkylation, 603
Trichloromethyl cation, X-ray studies, 171
Tricyclene, protonation of, 707
Tricyclo[4.1.0.01,3]heptyl cation, 224
Tricyclo[3.3.1.02,8]nona-3,6-dien-9-yl cations, 253
2,6-anti-Tricyclo[5.1.0.03,5]octan-2,6-diyl dication, 150
Tricyclopropylmethylium cation, 120
1H NMR spectrum of, 121
Triene, Ritter reaction of, 742
Trienol, cyclization of, 737, 738
Triethyloxonium tetrafluoroborates, alkylation with, 182, 324
Triethylselenonium fluorosulfate, 352
Triethylsilane
in ionic hydrogenation, 728
reductive cleavage with, 680
β-Triethysilylmethyl tropylium ion, X-ray studies, 161
para-Triethylditylthiolenium ion, 128, 402
Triflate esters, in alkylation, 551
Triflatoboric acid, 56. See Triflic acid–B(OSO2CF3)3
Triflic acid, 36, 38, 39. See also Trifluoromethanesulfonic acid and CF3SO3H
in acylation, 608–613
addition of, 741
in additions, 738–741
in alkenylation, 594
in alkylation, 336, 548, 750–752
Triflic acid (Continued)
in alkylation of aromatics, 554–556, 560–563, 574, 577–584, 592–595
in amination, 660
anchored to aminopropyl silica, 71
in acetylation, 611
in alkylation, 560
in aza-Mannich reaction, 751
in carbohydrate chemistry, 700–706
in cyclialkylation, 595–600, 602–607
in cyclization, 724
in cycloadditions, 736–738
in dehydrogenation, 698
in desulfurization of lignite, 543
in esterification, 734, 735
in formation of sulfoxides, 635
in formylation, 630, 631
in gasoline upgrading, 529
in generating
  carbodications, sulfur-stabilized, 194
  Cl₂CHC₇₀⁺ ion, 166
  fullerene cations, 165
  guanidinium ion, 201
  helicenium cation, 131
  hydrido-bridged cation, 250
  polytrityl cations, 152
in H–D exchange, regioselective, 220
impregnated into ZrO₂, 611
in iodination, 657, 658
and iodine, in coal liquefaction, 543
in ionic hydrogenation, 729
in isobutane–isobutylene alkylation, 585
in isomerization, 529, 530, 537–539, 750
in isomerization and transalkylation, 589
in Koch–Haaf reaction, 619
loaded into oxides, 71
in nitration, 638
in oxidative carbonylation, 626, 627
oxidative pathway in, 516
in oxygenation, 675, 676
in phenol–dienone rearrangement, 724
in polymerization, 745–750
preparation of, 38
in protection group chemistry, 676
in rearrangements, 725
in ring opening, 697
in Ritter reaction, 742, 743
superelectrophilic species, detected in, 693
in synthesis of heterocycles, 682–688, 690–694
in transacylation, 616
Triflic acid, silica-supported
in acetylation, 677
in alkylation, 551
in nitration, 638
Triflic acid–BF₃, in formylation–rearrangement, 631
Triflic acid–BiCl₃, in sulfonylation, 635

Triflic acid–B(OSO₂CF₃)₃
  in alkylation, 548, 578
  in isomerization, 535–537
  in nitration, 638
  in synthesis of homoallylic alcohols, 739
Triflic acid–HF–BF₃, 628
Triflic acid monohydrate, in electrochemical oxidation of alkanes, 524
Triflic acid–SbCl₃, in sulfonylation, 635
Triflic acid–SbF₅, 54, 55
  in additions, 741
  in alkylation of aromatics, 555, 577
  in cyclialkylation, 600, 601
dicatonic intermediates in, 580
in formylation, 628, 629, 631
in ionic hydrogenation, 729–733
in isomerization of alkanes, 535–537
in oxygenation, 675, 676
protonation curve in, 17
superelectrophilic species, detected in, 580
Triflic acid–trifluoroacetic acid, in acidity-dependence studies
  in alkylation, 551, 582, 583
  in cyclodehydration, 596–598, 604
Trifluorination, 651, 652
Trifluoroacetic acid, 375
  in acidity-dependence studies, 551, 582, 583, 583, 596–598, 604
  in acylation, 609
  in generating
    homotropylium ion, 160
    hydrido-bridged cation, 250
Trifluoroacetone
  methylation of, 187
  protonation of, 178
Trifluorodiazenium ion, 416
2,2,2-Trifluoroethylidiazonium ion, 384
Trifluoromethanesulfonic acid, see Triflic acid
Trifluoromethanol, 317
1-Trifluoromethyl-2-arylethanols, synthesis of, 562, 563
Trifluoromethylation, 566, 567
Trifluromethylbenzoyl chlorides, acylation with, 610
Trifluoromethyldiazomethane, protonation of, 384
Trifluoromethyl ketones, condensation—cyclization of, 695
Trifluoromethoxonium salts, 317
Triformamide, formylation with, 631
Trigermabicyclo bishomocyclopropenylium ion, 412, 413
Trihalomethyl cations, 170, 171
protonated, calculated structures of, 170
Trihalonium ions, 368
Trihaloselenonium ions, X-ray studies, 357
Trihalosulfonium ions, 340
Trihalotelluronium ions, X-ray studies, 357
Triheliomethyl trication, He₃C³⁺, calculations, 465
Trihydroxymethyl cation, see Carbonic acid, protonated
Trihydroxysulfonium ion, 343
Triiodomethyl cation salt, X-ray studies, 171
Triisopropylthiosilicenium ion, 401, 402
Trimercaptosulfonium salts, 346
Trimesityltelluronium cation, X-ray studies, 354
1,3,5-Trimethoxybenzene, as alkylating agent, 593
3,5,7-Trimethyladamant-1-yl cation, X-ray studies, 118
Trimethylbenzenes
cyclialkylation of, 595
monohydroxylation of, 664
2,4,6-Trimethylbenzyl cation, 142
2,2,3-Trimethylbutane, oxygenation of, 668
2,2,3-Trimethyl-2-butyl cation, 227
Trimethylene halonium ions, 374
Trimethylenenorbornane, endo–exo isomerization of, 535, 536
Trimethylethylene halonium ions, 373
1,3,5-Trimethylheptadienyl cation, cyclization of, 125
Trimethyl orthoformate, acetalization with, 678
Trimethyloxonium dication, calculated structure of, 325
Trimethyloxonium ion, 323–325 calculations, 325
intermediacy of, 327
Trimethyloxonium tetrafluoroborate, alkylation with, 182, 339, 353
Trimethylperoxonium ion, 330
Trimethylesselenonium fluorsulfate, 352
meta-Trimethylsilylanisole, desilylative acylation of, 617
Trimethylsilyl azide, as aminating agent, 660
Trimethylsilyl benzhydryl ethers, alkylation with, 752
1-(Trimethylsilyl)bicyclobutonium ion, 244
(Trimethylsilyl)methylhalonium ions, 364
[(Trimethylsilyl)methyl]oxonium ion, 318, 322
[(Trimethylsilyl)methyl]oxonium salts, 323
Trimethylsilyl perchlorate, 402
N-(Trimethylsilyl)pyroglutamate, alkylation of, 752
2-[(1-Trimethylsilyl)vinyl]-2-adamantyl cation, 139
Trimethyltelluronium fluorosulfate, 353
Trimethylthiocarbene ion, 194
Trioxide intermediate, in oxygenation with ozone, 667, 668
Triphenylmethane(s), formation of, 578, 579
Triphenylmethanol, formation of, 578
Triphenylmethyl cation, see Trityl cation
Triphenylmethyl chloride, ionization of, 83
Triphenyloxonium ions, 325
Triphenylsilyl perchlorate, 402
Triphosphonium ion, 421
Tris(1-adamantyl)methyl ion, 106
Tris(amine) boron dications, 400
Tris(dichloromethyl)amine, formylation with, 631
Tris(diformylamino)methane, formylation with, 631
Trishomocyclopropenyl cations, 265, 269 calculated structure of, 266
ethano-bridged, 266
Tris(methylthio)sulfonium hexafluoroantimonate, 346
Tris(naphthyl)methyl cations, 144
Tris(pentafluorophenyl) borane, 45
Tris(pentafluorophenyl)telluronium cation, 354
Trisphosphenium trications, 422
Tris(2,3,5,6-tetramethylphenyl)Snþ ion 414
Tris(2,4,6-triisopropylphenyl)Snþ (C6F5)4B– salt, X-ray studies, 414
Tris(trimethylsilyl)cyclopropenium ion, X-ray studies of, 157
Triterpenoids, synthesis of, 706
Trityl cation, 140
  hydride abstraction with, 161, 187, 194, 268, 398, 402, 403, 405, 407, 415 420
  X-ray studies of, 140
Tropinone, alkylation with, 581
Tropylium ion, 158–160
  generation of, by hydride abstraction, 144
  in MS studies, 142
  b-triethylsilylmethyl-substituted, 161
Tryptamine derivatives, hydroxylation of, 665
Tryptophane derivatives, hydroxylation of, 665
Two-electron oxidation
  of alkanes, 524
  of anthracenes, 163
  of biphenylenes, 161
  in generating
    diselenonium dication, 359, 360
    disulfonium dications, 358
    ditelluronium dication, 359
    1,2-dithin dication, 348
    fullerene cations, 166
    metal carbonyl cations, 457
  of isopentane, 520
  of naphthalenes, substituted, 163
  of pagodane, 262, 263
  of tetrakis(dimethylamino)ethylene, 203
  of tetrasubstituted ethylenes, 155
Two-electron–three-center bonding, 85, 144, 505
  in alkane isomerization, 527, 538, 539
  in exchange between H2 and D2, 460, 505
  in H–D exchange, 220, 410, 411, 505, 510, 511
  in µ-hydride bridged cations, 250–252
  in methane cations, 208–210, 212–215
  in methylenonium dications, 363
  in nitration, 637
  in 2-norbornyl cation, 229, 231, 239
  in protonated
    butanes, 220–223
    ethanes, 216, 217
    propanes, 218, 219
Undecatetraenes, Diels–Alder reaction of, intramolecular, 737
Unsaturated amines, alkylation of benzene with, 554
α,β-Unsaturated carbonyl compounds, as alkylation agents, 555
α,β-Unsaturated carboxamides
  alkylation of benzene with, 554
  ionic hydrogenation of, 732
Unsaturated carboxylic acids, acylation of, 613
α,β-Unsaturated ketones
  formation of, 752
  in ionic hydrogenation of, 732
  Michael addition of, 738
  protonation of, 625
Urea, protonation of, 196, 197
Uronium ions, 196, 197
UV spectroscopy
  for acidity measurement, 13, 28, 39, 40, 53, 64
  for carboxocations, 94, 104, 140, 151
  for onium ions, 322, 428–431
UV–visible spectroscopy, 5, 24, 54
  for carboxocations, 126, 145
  for onium ions, 427, 440, 444
Vibrational spectroscopy, 437, 440, 455, 457
Vinca alkaloids
  fluorination of, 652–654
  ionic hydrogenation of, 732
Vincadifformine, hydroxylation of, 666
Vindoline, ring formation of, 681
Vinorelbine, difluorination of, 654
Vinyl cation(s), 134, 594
  charge delocalization in, 136
  Coulomb-explosion imaging of, 134, 135
  β,β′-disilylated, X-ray studies, 138
Vinyl cation(s) (Continued)
\(\alpha\)-mesityl-\(\beta\)-silyl-substituted, 137
mesomeric, 134, 135
\(\beta\)-silylated, 137
stabilized, 136
viny-substituted, 136, 137
Vinylcyclopropenyl cation, 267
Vinyldiazonium ions, 385
Vinyl ethers, polymerization of, 750
1-Vinylidene cation, 626, 627
Vinylxenon compound, acyclic, 463
Vinylxenonium ions, fluorinated, 463
Vol’pin’s systems, see Aprotic organic superacids
Voltammetry, 520

Wagner–Meerwein
phenyl migration, 697
shift, 92, 230, 233–235, 697, 707
[\(W\)(CO)\(_6\)\(\{FSbF_5\}\)]\(^{+}\)\(\text{Sb}_2\text{F}_{11}^-\) salt, X-ray studies, 457
\(\text{WO}_3\cdot\text{Al}_2\text{O}_3\), in methyl alcohol into gasoline, 327

Woodward–Hoffmann transition states, 263, 264

\(\text{Xe}_i^{+}\) cation, 461
\(\text{Xe}_n^{+}\) cations, in mass spectrometry, 461
\(\text{XeCl}^{+}\)\(\text{Sb}_2\text{F}_{11}^-\) salt, 464
\(\text{XeF}^{+}\) cation, 463
\(\text{XeF}_3^{+}\) cation, 463
\(\text{XeF}_3^{+}\) cation, 463
\(\text{XeF}_5^{+}\) cation, 463
\(\text{XeF}_2\text{I}_{11}^{+}\) cation, 463
\([\text{Xe}(2.6\text{-F}_2\text{C}_6\text{H}_3)]^{+}\text{TFO}^-\) salt, X-ray studies, 462

\(\text{XeF}^{+}\)\(\text{MF}_{6}^-\) salts
oxidation with, 432
oxidative fluorination with, 318, 333, 335, 341, 450
\(\text{Xe}_2\text{H}_3^{+}\) calculations, 461
\(\text{XeH}^{+}\) cation, 461
\(\text{Xe}_2\text{H}^{+}\) cation, studies by cryogenic matrix isolation, 461
\(^{129}\text{Xe}\) NMR, 463
\(\text{XeOF}^{+}\) cation, 463
\(\text{XeO}_2\text{F}^{+}\) cation, 463
\(\text{XeOH}^{+}\) ion, 464
\(\text{XeO}^{+}\) ion, 464

\(\text{XeOO}^{+}\) ion, 464
\(\text{XeOTeF}_3^{+}\) cation, 463
\(\text{Xe}_2\text{OTeF}_3^{+}\) cation, 463
Xenodeborylation, 461, 462
Xenodeprotonation, 462
Xenon fluorides, 463
Xenonium ions, bonded to nitrogen, 464
Xenon oxyfluorides, 463

\([\text{XeN(SO}_2\text{F})_2]^{+}\)\(\text{AsF}_6^-\) salt, 464
\([\text{XeN(SO}_2\text{F})_2]^{+}\)\(\text{Sb}_3\text{F}_{16}^-\) salt, 464
\(\text{Xe}_2^{+}\)\(\text{Sb}_2\text{F}_{21}^-\) salt, X-ray studies, 461
\(\text{Xe}_2^{+}\)\(\text{Xe}_n\) aggregates, 461
\(\text{X}_3\text{FPSMe}^{+}\)\(\text{MF}_6^-\) salts, 396
\(\text{XF}_6^{+}\)\(\text{Sb}_2\text{F}_{11}^-\) salts, X-ray studies, 438
\(\text{X}_3\text{PH}^{+}\)\(\text{As}_2\text{F}_{11}^-\) salt, X-ray studies, 394
X-ray crystallography, 127

X-ray crystal structure of
alkoxycarbenium ions, 188
…

INDEX 849
X-ray crystal structure of (Continued)
nitrilium ions, 202
noble gas cations, 461–465
norbornyl cation, tetramethyl, 238
onium salts, 324, 333, 337, 338, 344,
353–355
oxonium salts, 184, 318, 324, 327
tert-pentyl cation, 107
2-phenyladamant-2-yl cation, 115
polyatomic cations, 440–445
polyheteroatom cations, 446–453
silicenium ions, 404–406
β-triethylsilylmethyl tropylium ion, 161
trihalomethyl cations, 171
3,5,7-trimethyladamant-1-yl cation, 118
trityl cation, 140
meta-xenium ion, 127
X-ray diffraction, 91
meta-Xylene
acylation of, 618
formylation of, 629
sulfonylation of, 634
para-Xylene
acylation of, 609, 615
alkylation of, 559, 566
Xylenes
alkylation of, 565
cyclalkylation of, 595
formylation of, regioselective, 630
monohydroxylation of, 664
meta-Xylenium ion, X-ray studies, 127
Yb(OTf)₃, alkylation of aromatics with, 560
Yohimbine, hydroxylation of, 666
Zeolite β, 554, 734
Zeolites
acidity of, 28, 29, 64
cyclalkylation of, 595
D₂O-exchanged, 517, 518
isomerization on, 530, 531
Zeolitic acids, 64, 65
Zn(CN)₂, 628
ZrO₂, impregnated with triflic acid
in acetalization, 676, 677
in acylation of aromatics, 611
ZSM-5, 554
